

17 Greenland Halibut in Subareas 5, 6, 12, and 14

Greenland halibut in ICES Subareas 5, 6, 12 and 14 are assessed as one stock unit although precise stock associations are not known.

17.1 Catches, Fisheries, Fleet and Stock Perception

17.1.1 Catches

Total annual catches in Divisions 5.a, 5.b, and Subareas 6, 12 and 14 are presented for the years 1981–2020 in Tables 17.2.1–17.2.6 and since 1961 in Figure 17.2.1. Catches decreased in 2020 by 4% to 22 669 t. Landings in Iceland waters (usually allocated to Division 5.a) have historically predominated the total landings in areas 5+14, but since the mid-1990s also fisheries in Subarea 14 and Division 5.b have developed. Total landings have since 1997 been between 20 and 31 kt.

17.1.2 Fisheries and fleets

In 2020 quotas in Greenland EEZ and Iceland EEZ were almost utilized as in the preceding fishing years. In the Faroe EEZ the fishery is regulated by a fixed number of licenses and technical measures like by-catch regulations for the trawlers and depth and gear restrictions for the gillnetters. Catches in 5b decreased slightly in 2020 from 1986 t to 1919 t.

Most of the fishery for Greenland halibut in Divisions 5.a, 5.b and 14.b is still a directed trawl fishery, but a gillnet fishery has gained importance in Iceland where the proportions of both gillnets and longlines have increased especially in the northern area, where the catches in gillnets are now more than 50% of the catches in 5a. Only minor catches in 5a and 14b are taken as by-catches in a redfish fishery (see section 22 on Greenland slope redfish). No or insignificant discarding has been observed in this fishery.

Spatial distribution of the 2020 fishery and historic effort and catch in the trawl fishery in Subareas 5, 6, 12 and 14 is provided in Figures 17.2.2–3. Fishery in the entire area did in the past occur in a more or less continuous belt on the continental slope from the slope of the Faroe plateau to south-east of Iceland extending north and west of Iceland and further south to southeast Greenland. Fishing depth ranges from 350–500 m southeast, east and north of Iceland to deeper than 1000 m at East Greenland (Figure 17.2.4). In recent years and in 2020 the distribution of the fishery covered all areas but bottom trawling has moved towards a more discontinuous distribution. Catches by gillnets has increased substantially in 5.a, north of Iceland and in 2019–20 a significant part of the landings were from gillnets (Figure 17.2.5).

In 2001–2008 a directed and a by-catch fishery by Spain, France, Lithuania, UK and Norway developed in the Hatton Bank area of Division 6.b, however, most of these fisheries ceased after 2008. Presently UK and France have a small fishery in the area. All catches in Subareas 6 and 12 are assumed to derive from the Hatton Bank area (Tables 17.2.5–17.2.6).

17.1.3 By-catch and discard

The Greenland halibut trawl fishery is mostly a clean fishery with little by-catches. Eventual by-catches are mainly redfish and cod. Southeast of Iceland the cod fishery and a minor Greenland halibut fishery are coinciding spatially. In East Greenland where fishery is located on the steep

slope, fishing grounds for cod and redfish are close to the Greenland halibut fishing grounds, but nevertheless the catches from single hauls are clean catches of Greenland halibut.

The mandatory use of sorting grids in the shrimp fishery in Iceland since the late 1980s and in Greenland since 2002 was observed to have reduced by-catches considerably. Based on few samplings in 2006–2007, scientific staff observed by-catches of Greenland halibut to be less than 1% compared to about 50% by weight observed before the implementation of sorting grids (Sünksen, 2007). No information has since been available but the fishery in Division 14b generally report discard rates less than 1% by weight in logbooks.

17.2 Trends in Effort and CPUE

17.2.1 Division 5.a

Indices of CPUE for the Icelandic trawl fleet directed at Greenland halibut for the period 1985–2020 is provided in Table 17.3.1 and Figures 17.3.1–2. The overall CPUE index for the Icelandic fishery is compiled as the average of the standardised indices from four areas.

Catch rates of Icelandic bottom trawlers decreased for all fishing grounds during 1990–1996 (Figure 17.3.1), but have since peaked in 2001 and have in recent years been variable without a trend. The overall tendency is the same for four areas in 5a (Figure 17.3.2). In 2020 all areas but the south-east area increased significantly. The southeast area had a decrease in CPUE, however since this is only based on 4 hauls, the southeast area was omitted from the average calculation (used as input to the assessment).

17.2.2 Division 5.b

Information from logbooks from the Faroese otterboard trawl fleet (>1000 hp) was available for the years 1995–2020 (Table 17.3.1, Figure 17.3.3.). The bulk of the fishery has historically been on the south-east slope of the Faroe Plateau. CPUE has decreased drastically since 2009 coinciding with a significant increase in effort. Since a record low CPUE in 2018, catch rates have slightly increased in 2019 and 2020.

17.2.3 Division 14.b

CPUE and effort from logbooks in area 14 are provided in Table 17.3.1 and Figure 17.3.4–5. Following a period with relatively low After a record high in 2016 CPUE slightly decreased in 2017–2020 although still high.

CPUE series from Divisions 5a, 5b and 14b show different trends over the time indicating that the populations/areas could have different dynamics.

17.2.4 Divisions 6.b and 12.b

Since 2001 a fishery developed in Divisions 6.b and 12.b in the Hatton Bank area by Spain, UK and France. The recent catches are stable but small. Limited fleet information is available from this area (ICES WGDEEP).

17.3 Catch composition

Length compositions of catches from the commercial trawl fishery in Division 5a are rather stable from year to year. In Figure 17.3.1 length distributions are shown since 1996 from Icelandic trawlers. Norwegian length measurements are available for Subarea 14 and France has provided length measurements from Division 6.a.

17.4 Survey information

Three surveys are conducted in the distribution area of the Greenland halibut stock; in East Greenland (14.b), in Iceland waters (5.a) and in Faroese waters (5.b). The total surveyed area is provided in Figure 17.4.1. The two surveys in 5.a and 14.b are combined to one index and used as biomass index input for the assessment model. Since the Greenland survey in 14.b has not been conducted since 2016, the index from 2016 are used onwards. The distribution of the historic catch rates from the two surveys are provided in Figure 17.4.2.

17.4.1 Division 5.a

Since 2006 the total biomass of Greenland halibut has increased significantly in Icelandic waters until 2017 (Figure 17.4.3). In 2018 and 2019 the total biomass decreased significantly mainly due to lower abundance of smaller fish (less than 40 cm), but in 2020 biomass increased again (Figures 17.4.3 and 17.4.4). Given the continued low abundance of smaller fish, a decrease in total biomass is expected in the near future.

Catch composition data is available from the survey in Icelandic waters are illustrated in Figures 17.4.4 (size) and 17.4.5 (age).

17.4.2 Division 5.b

The catch rates from the available time series of the Faroese survey have declined from a record high level in 2012–13 to low levels in recent years. (Figure 17.4.6). Decreasing catch rates are also seen for the southeastern part of Iceland waters adjacent to division 5.b indicating a declining stock in this eastern part of its distribution area.

17.4.3 Division 14.b

The Greenland survey have not been conducted since 2016 due to out phasing of old research vessel and lack of ability to get vessel replacement for the years since then. It is expected that a new research vessel will be in operation in 2022. From 1995 to 2016 the total biomass index from this survey in 14.b did show a decreasing trend. The stock annex provides more extensive descriptions of all surveys.

17.5 Stock Assessment

17.5.1 Stock production model

The assessment uses a stochastic version of the logistic production model and Bayesian inference according to the Stock Annex in which a more detailed formulation of the model and its performance is found.

17.5.1.1 Input data

The model synthesizes information from input priors and two independent series of Greenland halibut biomass indices and one series of catches by the fishery (Table 17.5.1). The two series of biomass indices are a revised annually for use in assessment: a standardised series of annual commercial-vessel catch rates in 5a in 1985–2020, $CPUE_t$, and a combined trawl-survey biomass index (5a and 14b) for 1996–2020, $Isur_t$. From 2017 to 2020 the survey index is based on the Icelandic survey and the 2016 values from the Greenland survey due to lack of Greenland survey data (see section 17.4.3). This is a necessary approach since the combined survey index is a sum of the two indices.

Total reported catch or WGs best estimates in ICES Subareas 5, 6, 12 and 14 1961–2020 was used as yield data (Table 17.5.1, Figure 17.2.1). Since the fishery has no major discarding problems or misreporting, the reported catches were entered into the model as error-free.

17.5.1.2 Model performance

The model parameters were estimated (posterior) based on the prior assumptions (Table 17.5.2–3 and Figure 17.5.1). The data could not be expected to carry much information on the parameter P_{1960} – the initial stock size 25 years prior to when the series of stock biomass series start – and the posterior resembled the prior (Figure 17.5.1). The prior for K was updated but similar to previous estimates. However, the posterior still had a wide distribution with an inter-quartile range of 703–1042 kt (Table 17.5.3).

The posterior for MSY was positively skewed with upper and lower quartiles at 27 kt and 39 kt (Table 17.5.3). As mentioned above, MSY was relatively insensitive to changes in prior distributions.

The model was able to produce a reasonable simulation of the observed data (Figure 17.5.2). The probabilities of getting more extreme observations than the realized ones given in the data series on stock size were in the range of 0.04 to 0.95 i.e. the observations did not lie in the extreme tails of their posterior distributions (Table 17.5.4). Exceptions are observed for the survey in 1997 ($p = 0.95$) and in 2019 ($p = 0.04$). The 2020 observations have, however, high residuals for both indices (–8% and 24%) both outside or at the quartiles of the model estimate (Figure 17.5.2).

The retrospective runs suggest high consistency for both biomass and fishing mortality within $\pm 20\%$ (range 3% – 4.3%, Figure 17.5.3).

17.5.1.3 Assessment results

The time series of estimated median biomass-ratios starts in 1960 as a virgin stock at K ($2 \times B_{MSY}$, Figure 17.5.4–5). The fishery on the stock starts in 1961. Under continuously increasing fishing mortality the stock declined sharply in the mid-1990s to levels below the optimum, B_{MSY} . Some rebuilding towards B_{MSY} was then seen in the late 1990s. Since then the stock started to increase from its lowest level in 2004–5 of approx. 48% of B_{MSY} and has in recent years increased to nearly 80% of B_{MSY} . The median fishing mortality ratio (F/F_{MSY}) has exceeded F_{MSY} since the 1990s, but has in recent years decreased and are in 2020 below F_{MSY} (Figures 17.5.4–5 and Table 17.5.5–6). Relative fishing mortality can only be estimated with large uncertainty and the posteriors therefore also include values below F_{MSY} . However, the probability that F exceed F_{MSY} is high for most of the years.

17.5.2 Short-term forecast and management options

The assumed catches for the intermediate year (2021) is 25 000 t based on agreed TACs for Iceland and Greenland EEZ and a continued catch level in Faroese waters.

Assuming catches of 25 000 t in 2021, a fishery at F_{MSY} ($F / F_{MSY} = 1$) in 2022 will lead to catches of 26 650 t (Table 17.5.7). Fishing at this level in 2022 will result in a 1% increase in biomass in 2023 and an increase in advice of 13%.

Biomass scenarios at various catch options are provided in Figures 17.5.6–7. Catches below 30 kt is estimated to lead to an increase in biomass, while catches of 30 kt will remain biomass at current level over the next decade (Figure 17.5.7). Only catches of less or equal to 20 kt will lead the biomass to reach BMSY within the next decade (Figure 17.5.6).

The risk trajectory associated with ten-year projections of stock development assuming a maintained annual catch in the entire period ranging from 0 to 30 kt were investigated (Figure 17.5.6–7). The calculated risk is a result of the projected development of the stock and the increase in uncertainty as projections are carried forward. It must be noted that a catch scenario of a maintained constant catch over a decade without considering arrival of new biological information and advice is unrealistic.

Scenarios of fixed levels of fishing mortality ratios within the range of 0.3 to 1.7 were conducted and are shown in Figure 17.5.8. Present biomass is above the MSY $B_{trigger}$ (50% of BMSY) and a fishery at F_{MSY} is advised according the ICES MSY advice rule. Fishing at F_{MSY} will result in slowly increasing yield the next decade.

17.5.3 Reference points

Reference points are unchanged from last benchmark in 2013 (WKBUT, ICES 2013).

17.6 Management considerations

Available biological information and information on distribution of the fisheries suggest that Greenland halibut in East Greenland, Iceland and Faroe Islands might be separated into sub-populations but that they do mix between these. Recent information of tagging experiments in the Barents Sea suggests high mixing between the Barents Sea and Iceland. This connectivity is not accommodated for in the present assessment. At the forthcoming planned benchmark of the Greenland halibut stocks in this area (5,6,12 and 14) and the North East Arctic (1+2) scheduled for 2023, the stock identity of both stocks will be evaluated based on ongoing research projects.

A bilateral agreement between Iceland and Greenland since 2014 have limited the overall catches in recent years and assured that fishing pressure is around F_{MSY} . This agreement is no longer in place; however, Iceland and Greenland are following the agreement at large when setting TACs.

17.7 Data consideration and Assessment quality

The Icelandic CPUE series has for many years been used as a biomass indicator in the assessment of the stock. The CPUE of the Greenlandic trawlers and the biomass indices from the Faroese waters have not been used in the assessment, mainly because the stock production model is not able to accommodate contrasting indices (Icelandic CPUE and Greenlandic/Icelandic autumn surveys). A common analysis of all CPUE data from the stock area should possibly be utilized for a combined standardised CPUE index for the assessment. Likewise, the Faroese survey should be merged into a combined survey index. This lack of optimal usage of available information need to be solved at the next benchmark. Further work should also investigate effects of the changes in effort in 5.a as the proportion of landings from and distribution of effort of bottom trawls has been substantially reduced.

With the foreseen change to an age-based assessment more requirements will be put on biological sampling and sampling from the fisheries.

17.8 Research needs and recommendations

Stock structure and connectivity between the main fishing areas remains unquantified. Basic biological information on spawning and nursery grounds for the juveniles also remains poorly known. Trends of biomass indices over the entire assessment area are not similar and may suggest different dynamics between areas. Further, tagging experiments in the Barents Sea suggest a high connectivity with Iceland waters. Therefore, a compilation of present knowledge of stock identification for Greenland halibut in the East Greenland, Iceland, Faroese and Norwegian waters are being reviewed. Ongoing projects with trans-Atlantic participation from major fishery research institutes is presently analysing historic tag-recapture data with the objective to outline stock structure with focus on evaluating present stock entities in the entire North Atlantic. Further, stock structure are being investigated with several methods, such as. genetics, tagging, otolith microstructure, drift modelling and use of survey and fisheries data. These projects are running until 2022 and is expected to contribute with valuable biological information for the scheduled benchmark in 2023.

A number of issues on the quality of the input biomass indices to the present assessment model are questioned. The Icelandic CPUE series that is based on the principal trawler fleet is assumed to have undergone marked changes with respect to management regulations and spatial distribution. The possibility to estimate these effects by standardization of catch rates should be explored. Similar analyses should be conducted on the remaining CPUE series, in order to evaluate them as indicative of biomass development.

The present assessment model, a stock production model in Bayesian framework, is criticized for its behaviour in relation to the biomass indices. The models use of process error and sensitivity to various priors should be further scrutinized.

At the benchmark in 2013 (WKBUT, ICES 2013) an alternative assessment model, Gadget, was presented. Presently input to the Gadget model is not complete and the approach need further exploration and especially age data from the entire stock distribution area is required. The Gadget model will be a first alternative assessment model to the present stock production model at the next benchmark.

Ageing of Greenland halibut ceased for many of the marine institutes in Greenland, Iceland, Faroe Island and Norway around 2000 due to reading difficulties and lack of inter-calibration. A new method has been agreed upon and cooperation between institutes has been initiated in 2016 on age calibration. With respect to the Greenland halibut stock in 5,6,12 and 14 Iceland has now progressed so far that the 6 previous years otolith samplings has been read. The Greenland institute of Natural Resources has not yet begun ageing of otoliths from this stock. With an ALK some years back and assumptions on constant growth initial exercises with age-based assessment models should be conducted.

1) Provisional data

2) WG estimate includes additional catches as described in working Group reports for each year and in the report from 2001.

3) Includes 125 t by Faroe Islands and 206 t by Greenland.

4) Excluding 4732 t reported as area unknown.

5) Includes 1523 t by Norway, 102 t by Faroe Islands, 3343 t by Germany, 1910 t by Greenland, 180 t by Russia, as reported to Greenland authorities.

6) Does not include most of the Icelandic catch as those are included in WG estimate of Va.

7) Excluding 138 t reported as area unknown.

17.11 Figures

Fig. 17.2.1. Landings of Greenland halibut in Divisions 5, 6, 12 and 14. As the landings within Icelandic waters, since 1976, have not officially been separated and reported according to the defined ICES statistical areas, they are set under area 5a by the NWWG. In 2012 Icelandic landings in Div 14 were only partly recorded in 14, while for remaining years all landings are recorded in 5a.

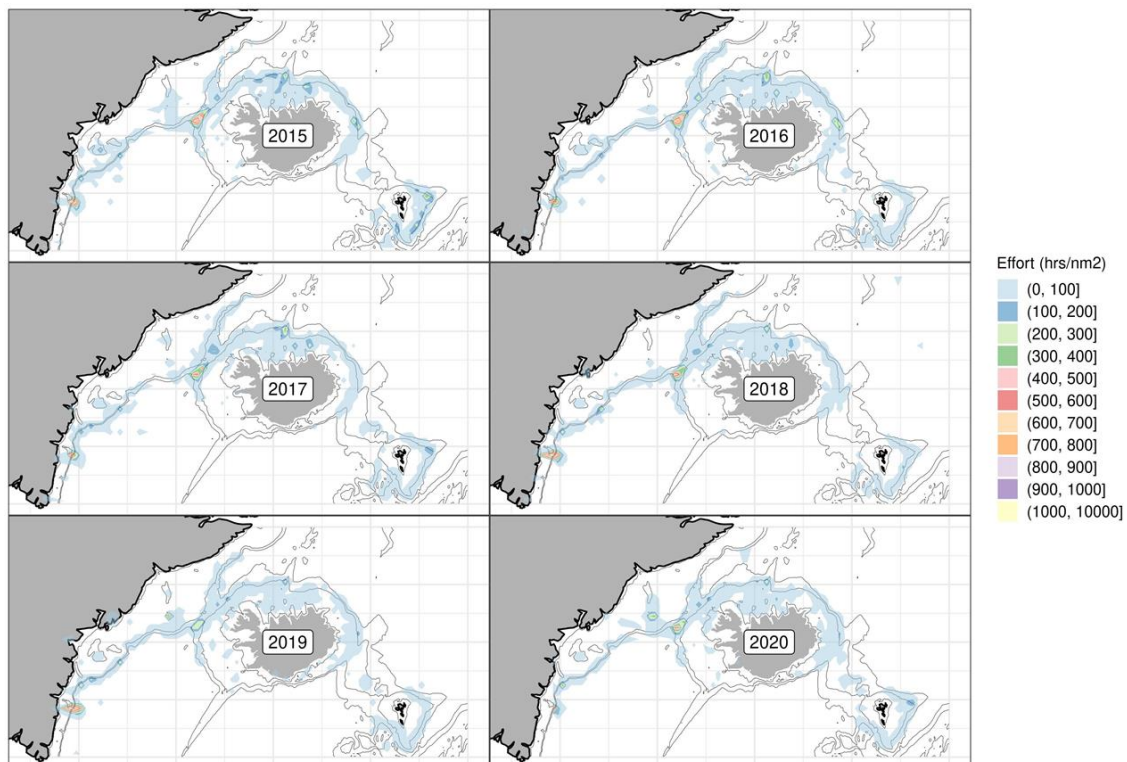

Fig. 17.2.2 Greenland halibut 5+14. Distribution of fishing effort 2015-2020. 500m and 1000 m depth contours are shown.

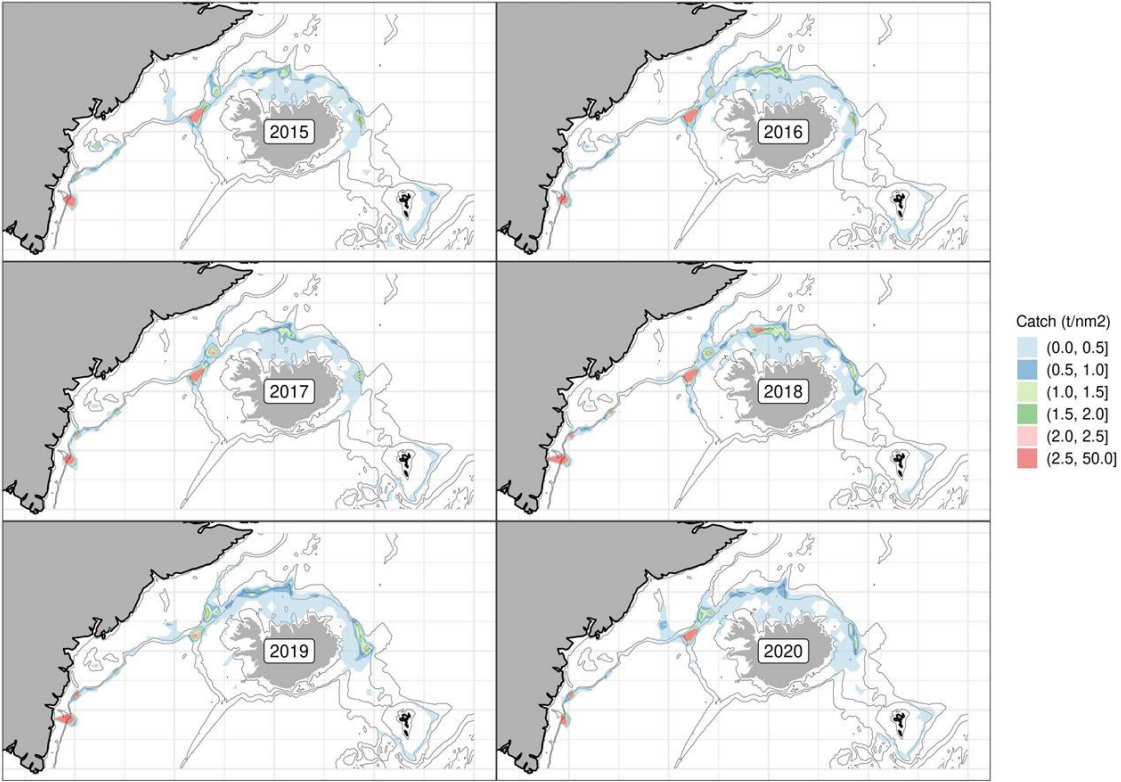

Fig. 17.2.3. Greenland halibut V+XIV. Distribution of catches in the fishery 2015-2020. 500m and 1000 m depth contours are shown.

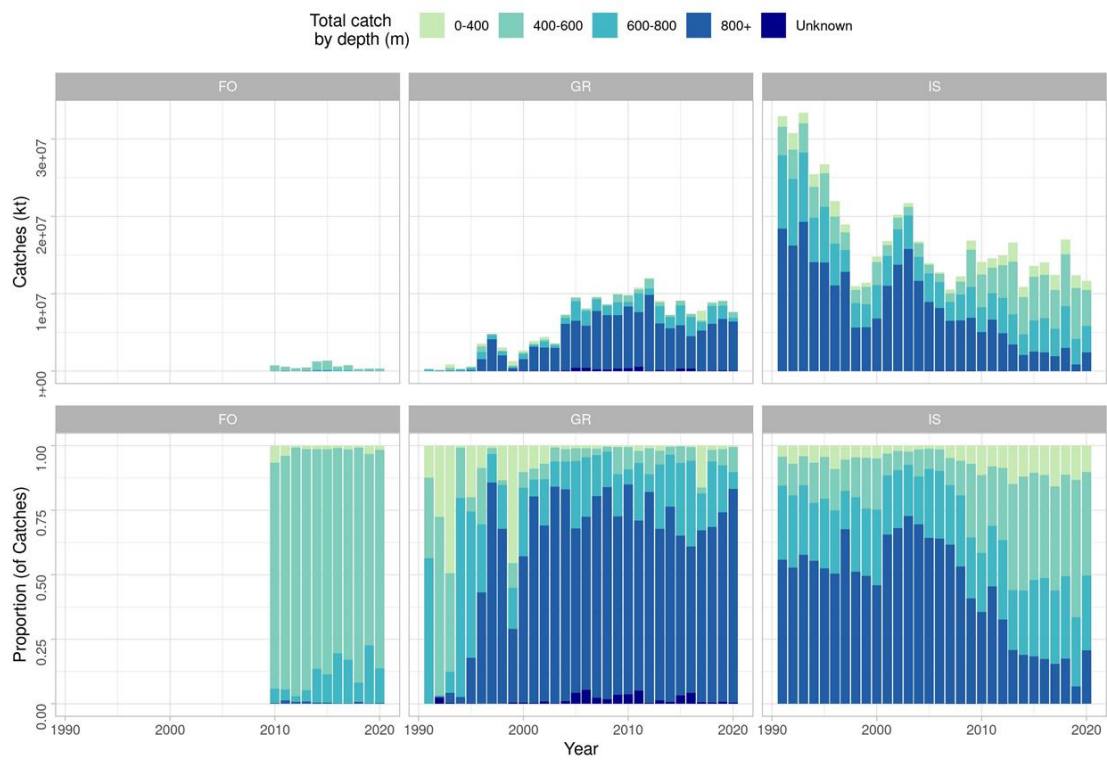

Fig 17.2.4. Greenland halibut 5+14. Depth distribution by EEZ from 1990 to 2020.

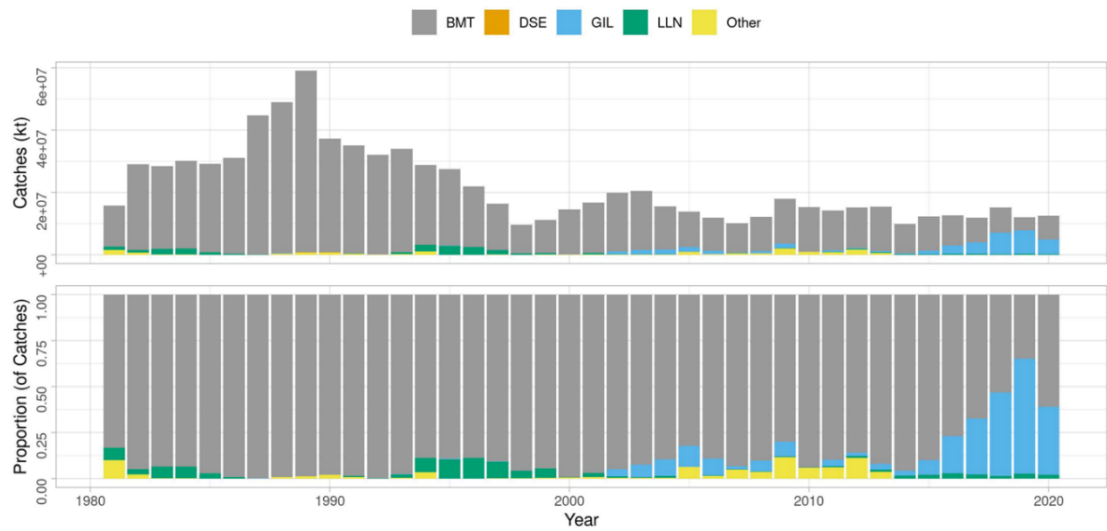

Fig. 17.2.5. Greenland halibut 5+14. Division of landings by gear in 5a.

Fig. 17.3.1. Standardised CPUEs from the Icelandic trawler fleet in 5a. Area 1-4 are west, north, east and south-east, respectively. The average index of the four areas is used as biomass indicator in the stock production model.

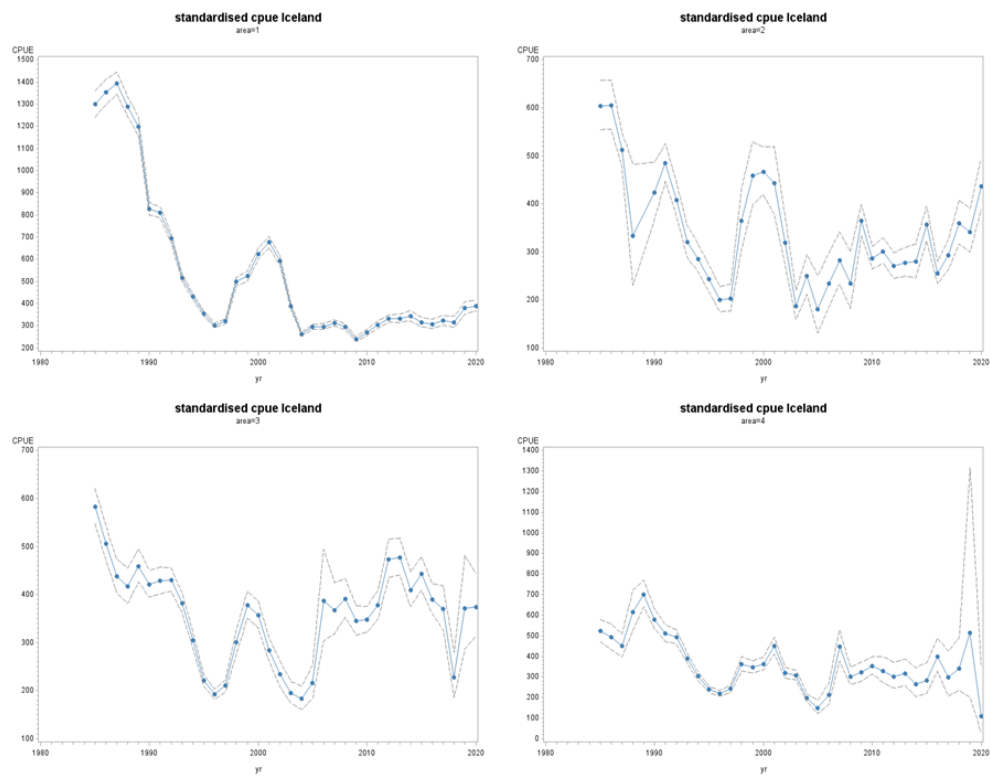

Fig. 17.3.2 Standardised CPUE from the Icelandic trawler fleet in Div 5a by four main fishing areas in 5a. 95% CI indicated. Areas 1-4 are West, North, East and South-east of Iceland, respectively.

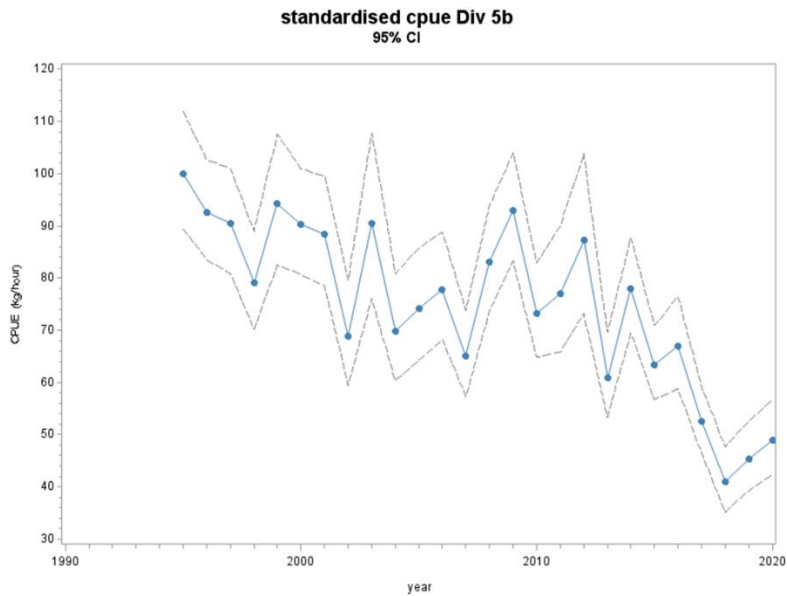

Figure 17. 3.3. Standardised CPUE from the Faroese trawler fleet. 95% CI indicated

Fig. 17.3.4. Standardised CPUE from trawler fleets in 14b. 95% CI and observed CPUE (avg) indicated.

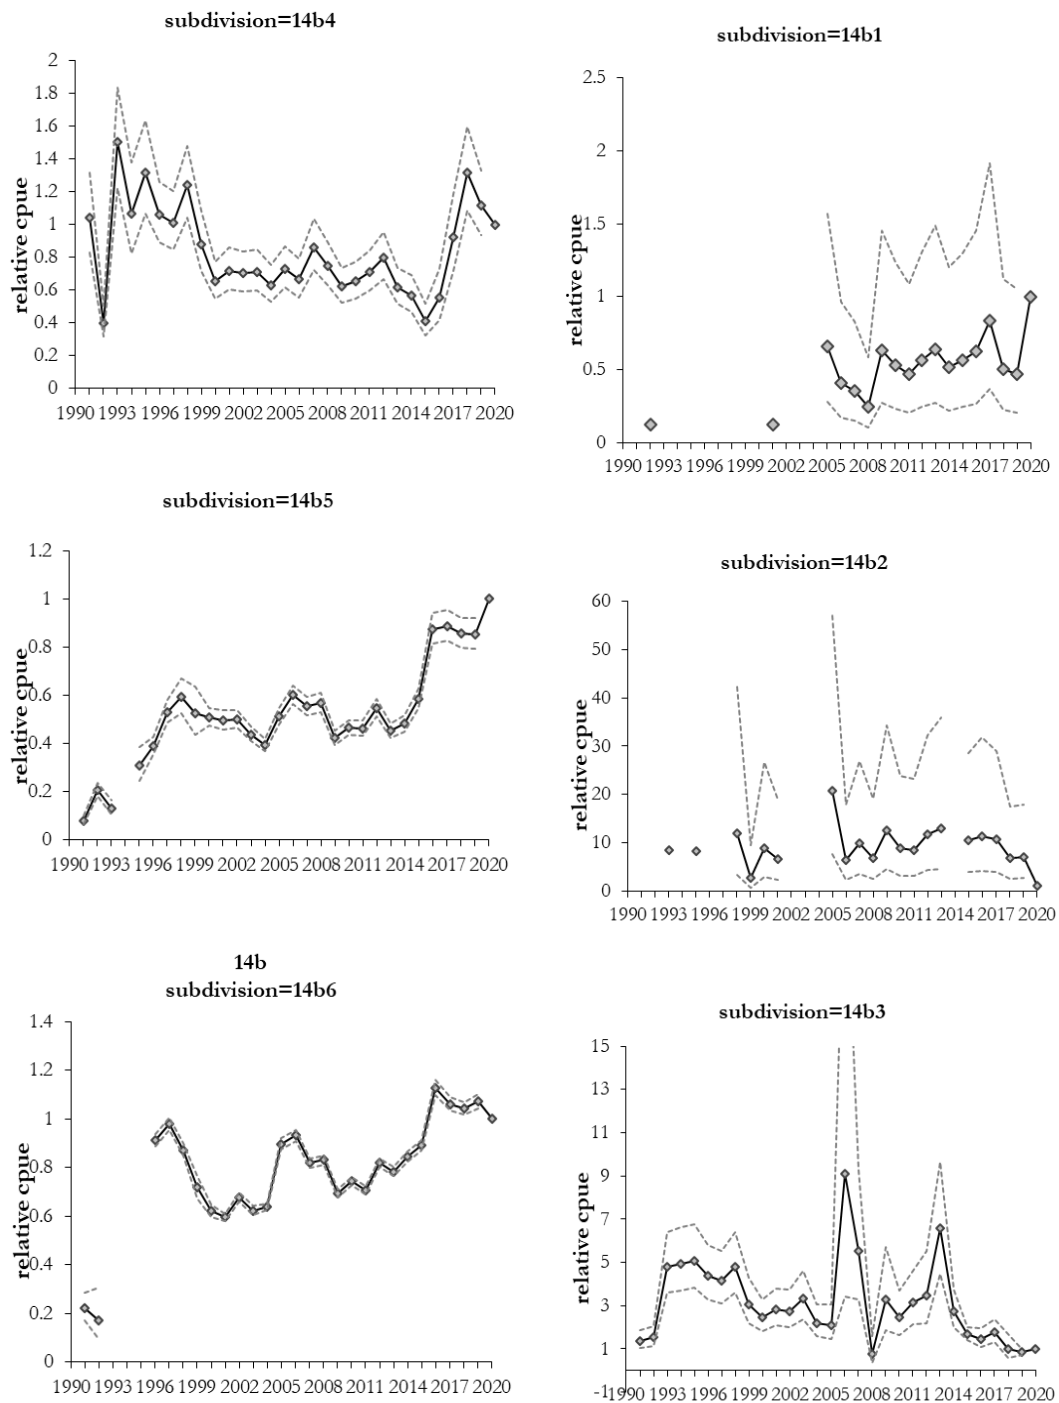

Fig. 17.3.5. Standardised CPUE from trawler fleets in 14b shown by subdivisions in a north-south direction. 95% CI indicated.

Fig. 17.3.1. Length distributions from the commercial trawl fishery in the western fishing grounds of Iceland (5a) in the years 2002-2019. Blue indicate males and red indicates females.

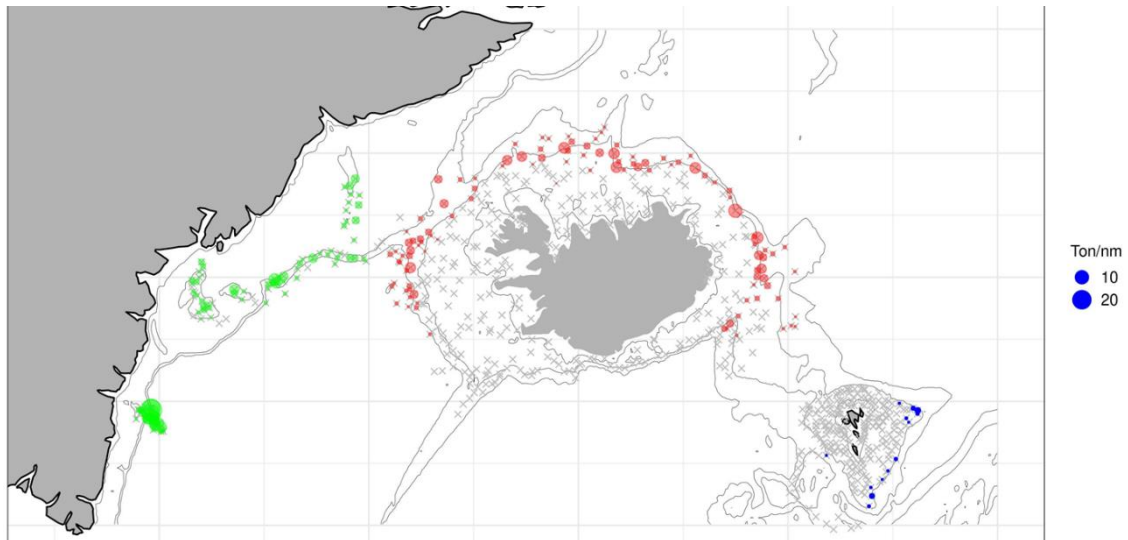

Fig. 17.4.1. Stations covered by scientific surveys in SA 5 and 14 in 2020 by Iceland (n=203). Red indicate Iceland survey, green is Greenland survey and blue is Faroe survey. Size of circles indicate catch rates and grey crosses are zero catches. The Greenland survey has not been conducted since 2016 and 2016 values are shown here.

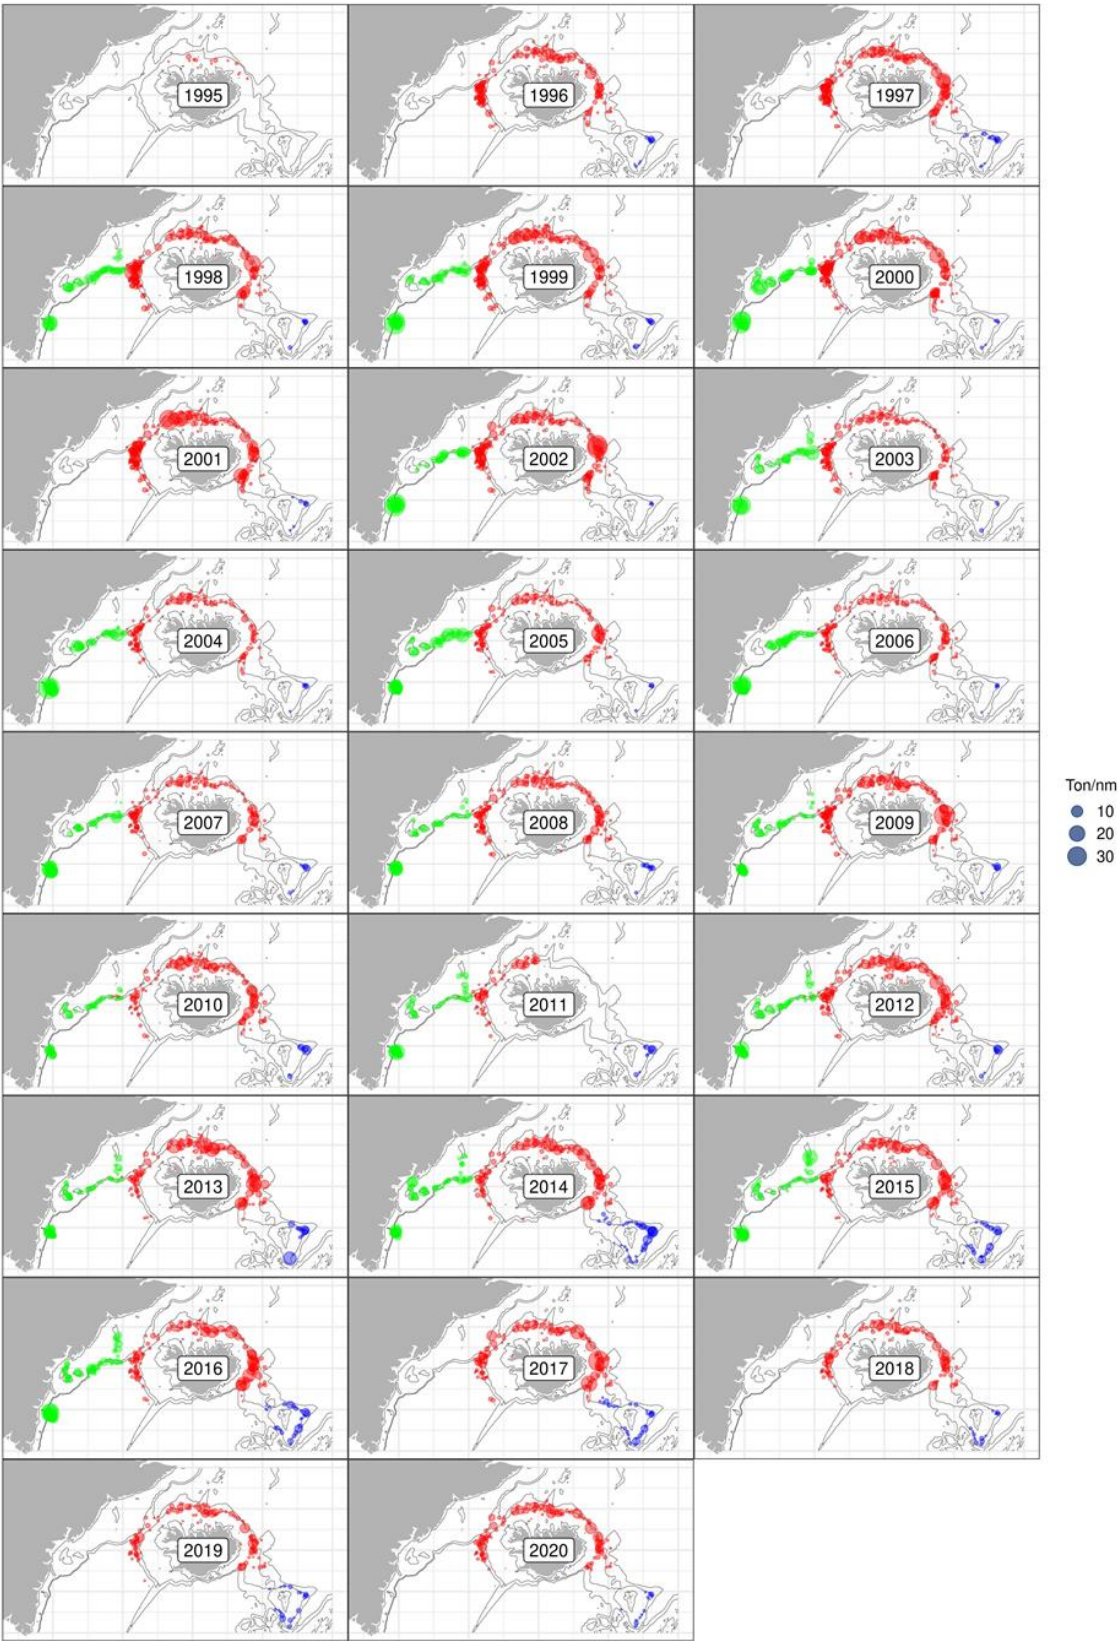

Fig. 17.4.2. Distribution of Greenland halibut catch rates from the combined Greenland-Icelandic fall survey since 1996.

Fig. 17.4.3. Index of Greenland halibut in the Iceland, Greenland and the combined survey. No Iceland survey was conducted in 2011 and Greenland survey ceased in 2016. Greenland survey values are considered constant since 2016.

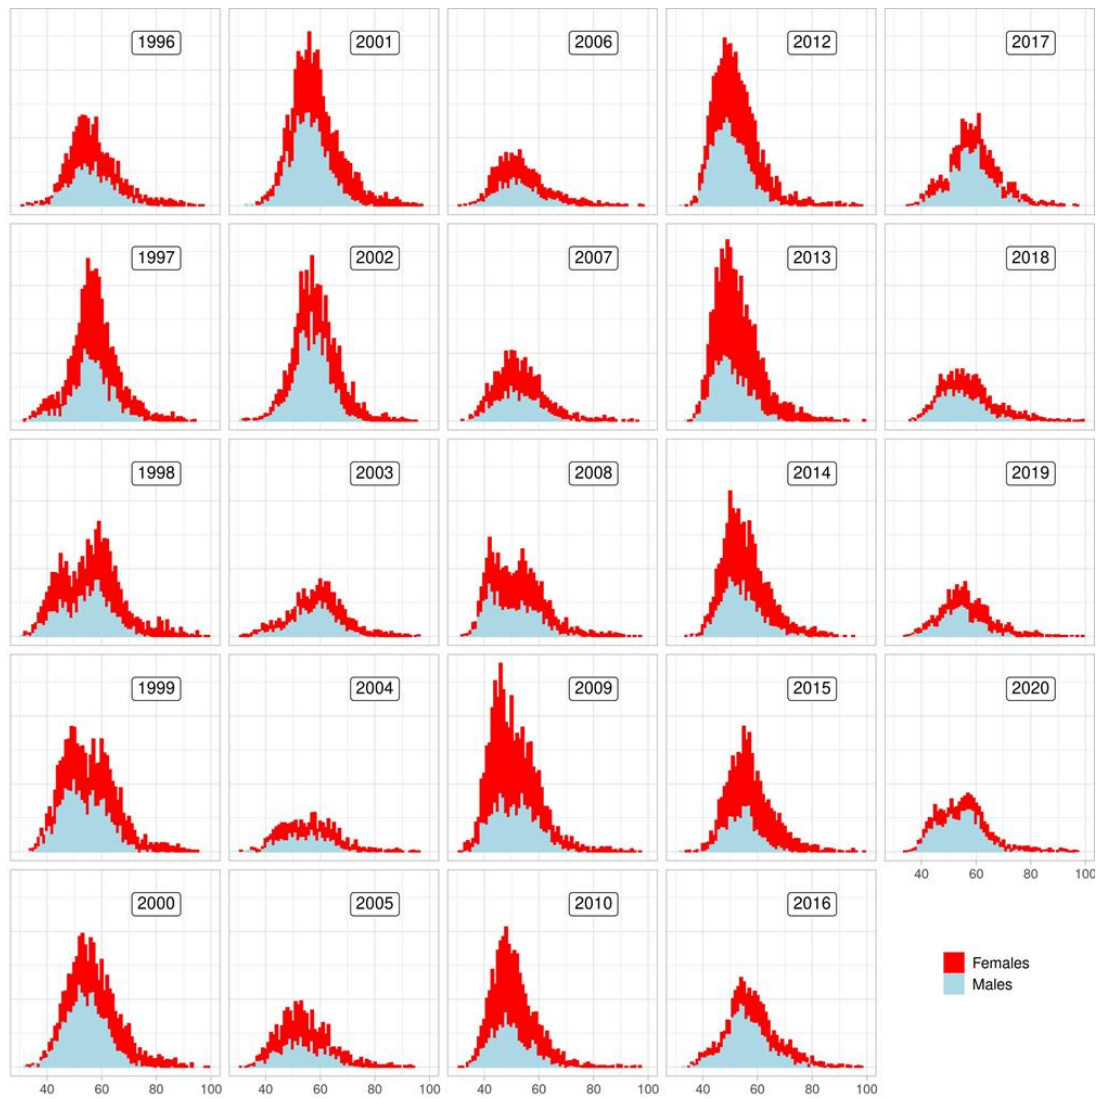

Fig. 17.4.4. Abundance indices by length for the Icelandic fall survey 1996-2020. No survey was conducted in 2011.

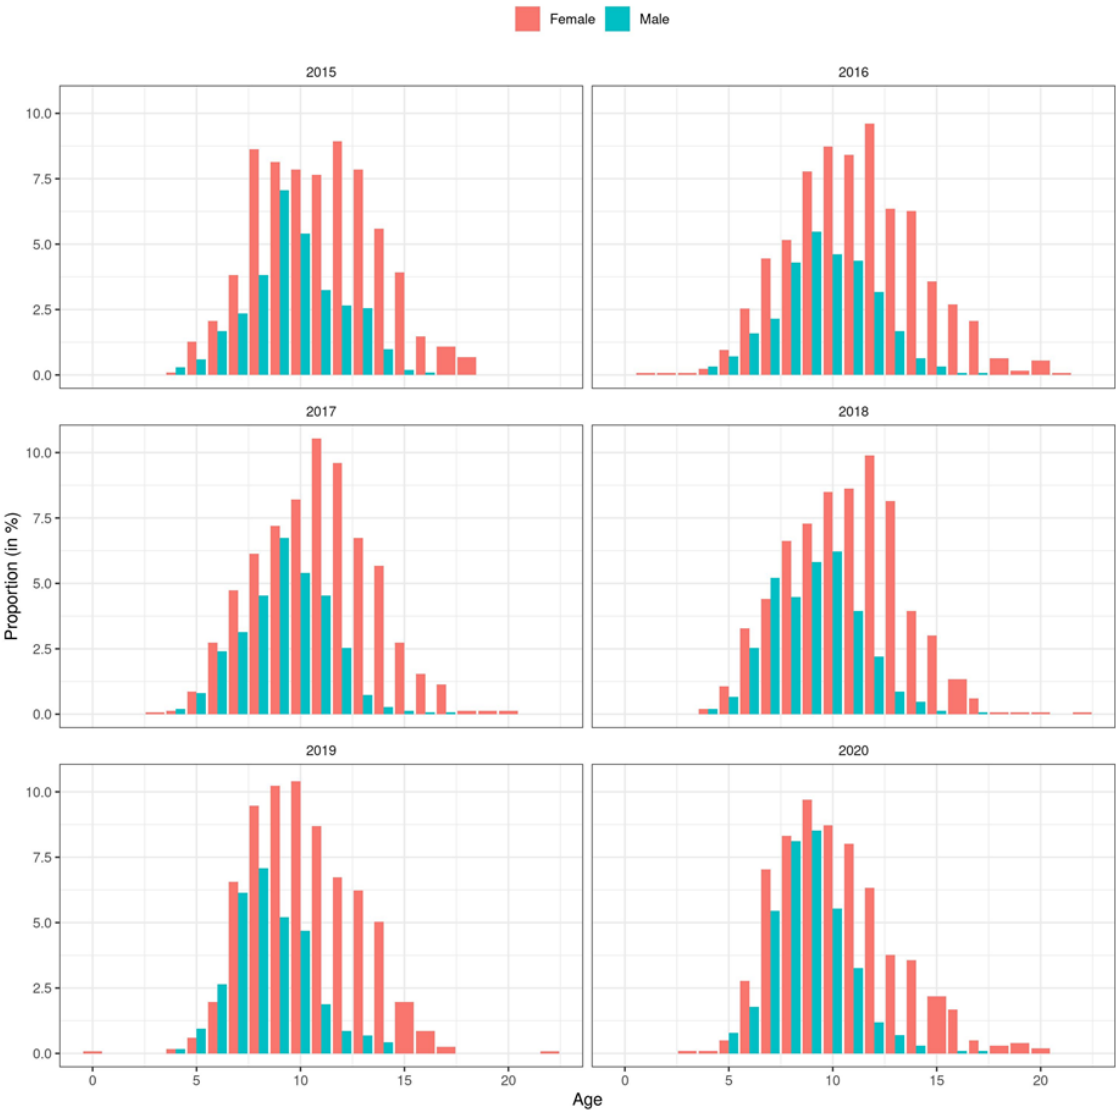

Figure 17.4.5. Age/sex distribution from Icelandic fall survey 2015-2020.

Figure 17.4.6. Standardised catch rates from a combined survey/fisherman’s survey in 5b..

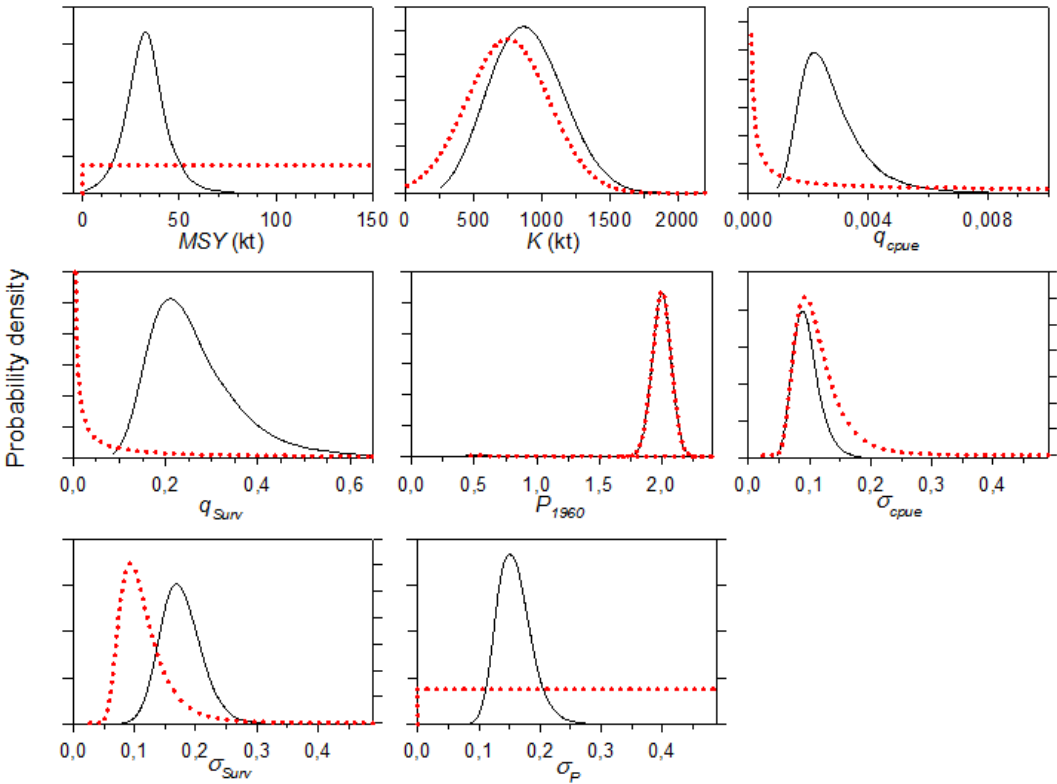

Figure 17.5.1. Probability density distributions of model parameters: estimated posterior (solid line) and prior (broken line) distributions.

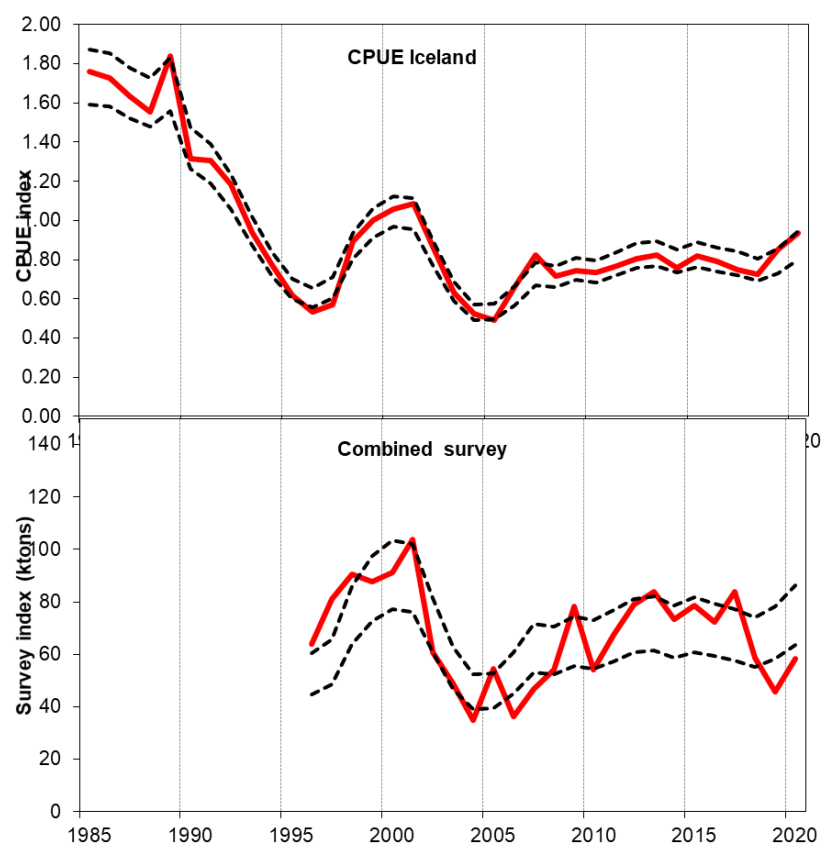

Figure 17.5.2. Observed (red curve) and predicted (dashed lines) series of the two biomass indices input to the model. Dashed lines are inter-quartile range of the model estimates.

Figure 17.5.3. Retrospective analyses of medians of relative biomass (B/B_{msy}) and fishing mortality (F/F_{msy})

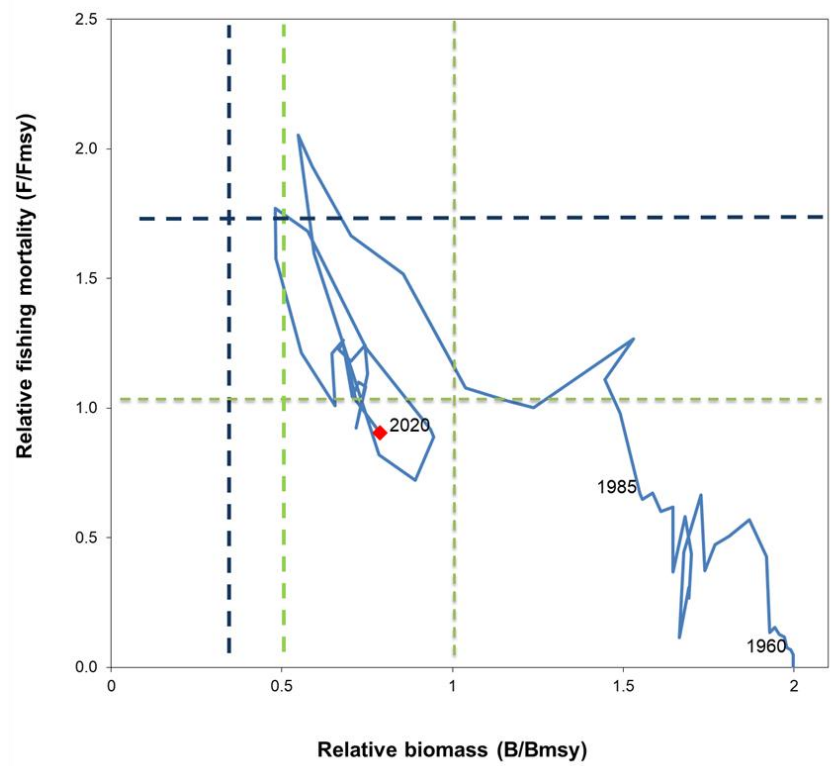

Figure 17.5.4. Stock trajectory 1960-2020. Estimated annual median biomass-ratio (B/B_{MSY}) and fishing mortality-ratio (F/F_{MSY}). B_{lim} , MSY , $B_{trigger}$ and F_{lim} are indicated.

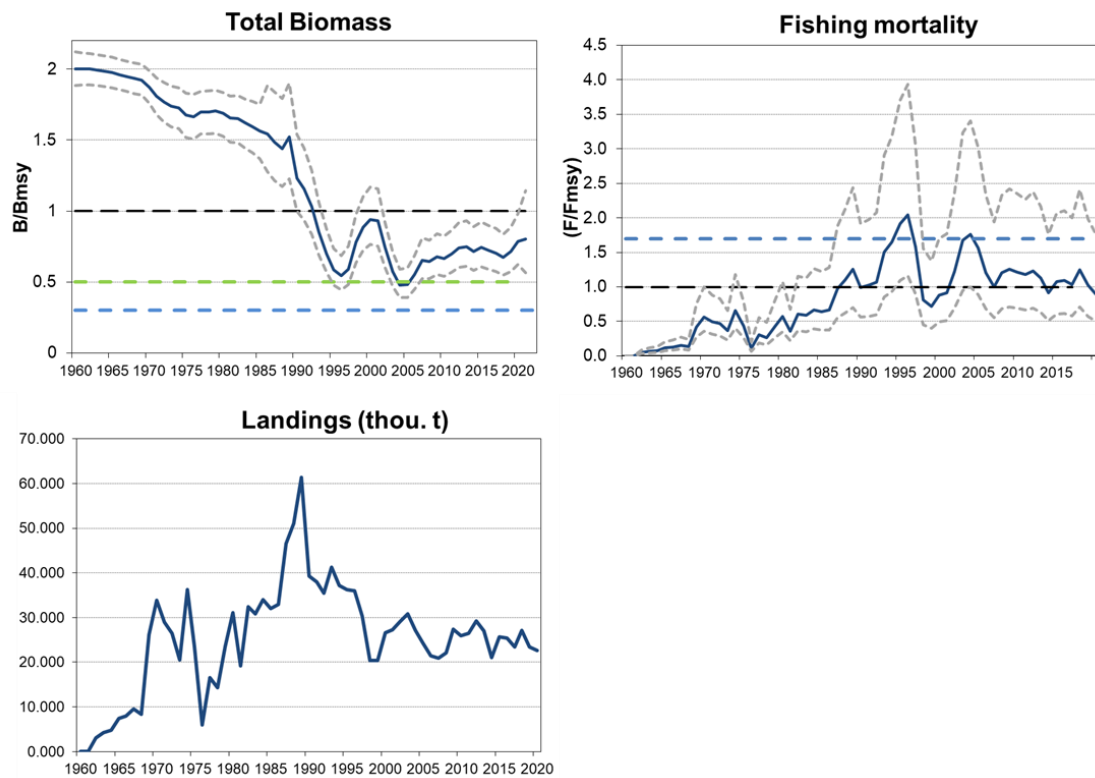

Figure 17.5.5. Stock summary, upper panel right: fishing mortality (F/F_{msy}) and 95% conf limits, left: total biomass (B/B_{msy}) and 95% conf limits and lower panel is landings since start of the fishery. MSY $B_{trigger}$ (green dashed line), B_{lim} and F_{lim} (blue dashed lines) are indicated.

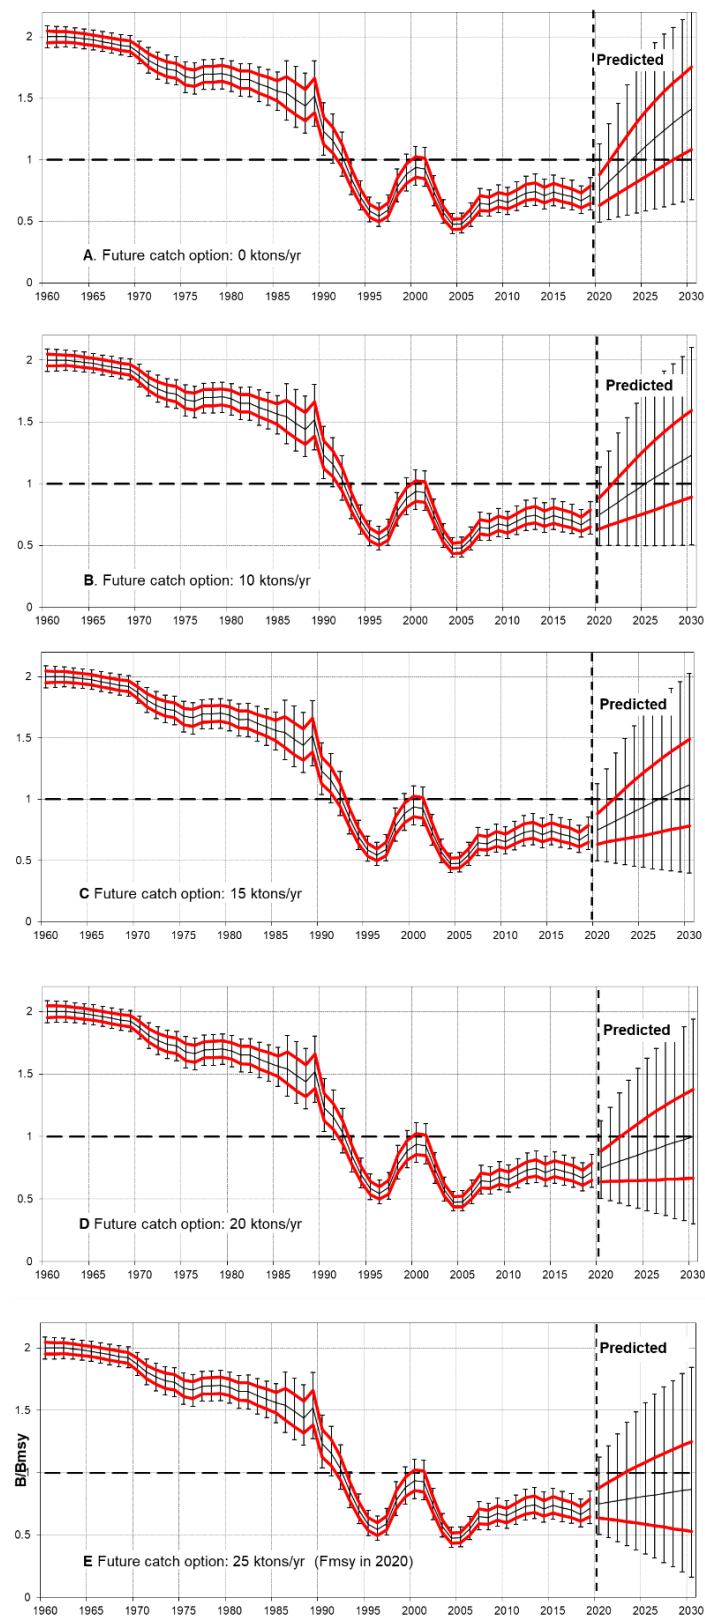

Fig. 17.5.6 Estimated time series of relative biomass (B_t/B_{msy}) under different catch option scenarios: 0, 10, 15, 20 and 25 kt catch from upper to lower panel. Bold red lines are inter-quartile ranges and the solid black line is the median; the error bars extend to cover the central 90 per cent of the distribution.

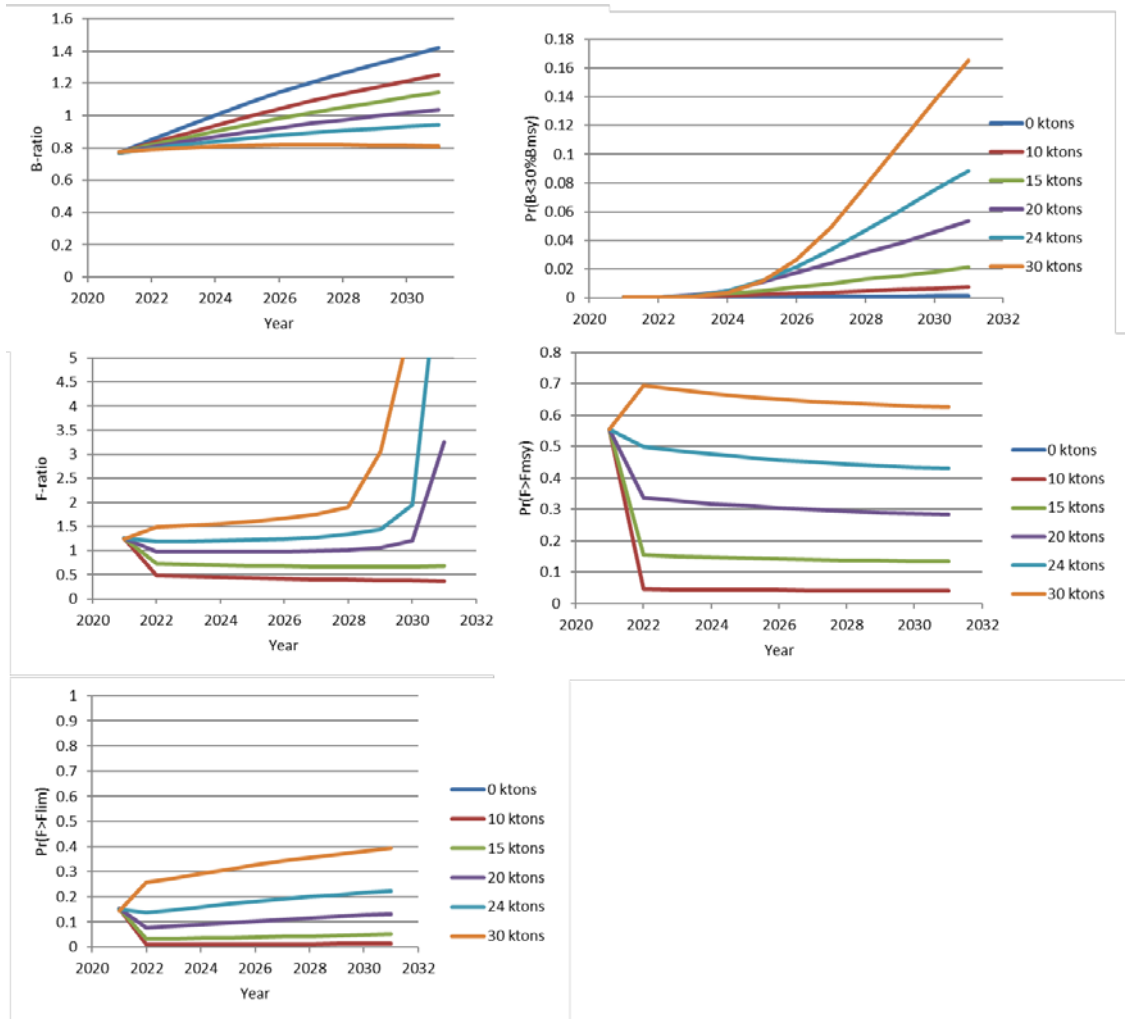

Figure 17.5.7. Projections: Medians of estimated posterior biomass- and fishing mortality ratios; estimated risk of exceeding F_{msy} or going below and $B_{MSYtrigger}$ given catch ranges at 0 -30 ktons.

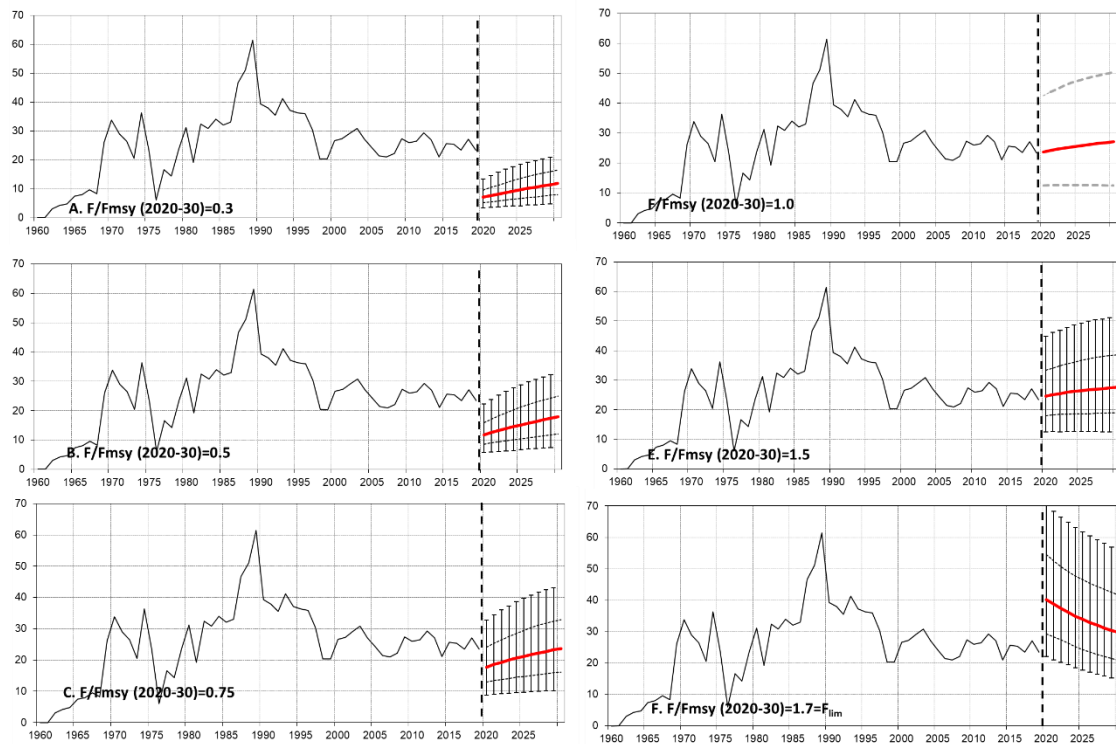

Figure 17.5.8. Historic landings and projected landings 2020-2030 under various F ratio options from 0.3-1.7 F/F_{msy} Solid red line is median, quartiles and 90% conf limit indicated.

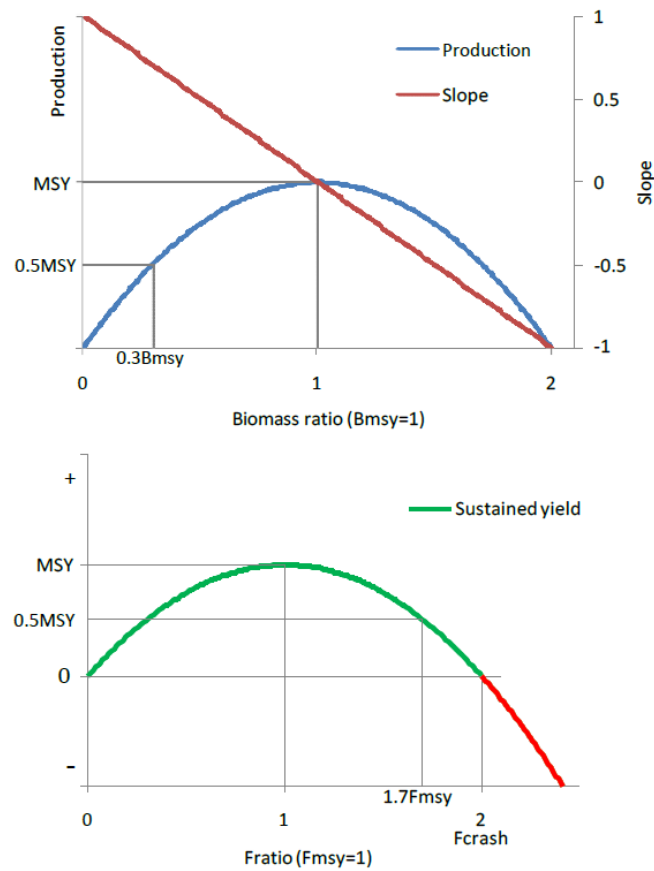

Figure 17.5.9. The logistic production curve in relation to stock biomass (B/B_{msy}) (*upper*) and fishing mortality (F/F_{msy}) (*lower*). *Upper*: points of maximum sustainable yield (MSY) and corresponding stock size are shown as well as the slope (red line) of the production curve (blue line); *lower*: points of MSY and corresponding fishing mortality and F_{crash} ($F \geq F_{crash}$ do not have stable equilibria and will drive the stock to zero).
