1 INTRODUCTION

1.1 Main Tasks

At its 1998 Statutory Meeting, ICES resolved (C. Res. 1998/2:4:11) that the Working Group on North Atlantic Salmon (Chairman: Dr T.L. Marshall, Canada) will meet in Québec City, Canada, from 12-22 April, 1999 to consider questions posed to ICES by the North Atlantic Salmon Conservation Organisation (NASCO). The terms of reference and sections of the report in which the answers are provided, follow.

a) With respect to Atlantic salmon in the North Atlantic area:	Section
i. provide an overview of salmon catches, including unreported catches and catch and release, and worldwide production of farmed and ranched salmon in 1998;	2.1 & 2.2
ii. evaluate non-catch fishing mortality for all salmon gear;	2.3
iii. report on significant developments which might assist NASCO with the management of salmon stocks;	2.4
iv. develop a framework for stock rebuilding programmes;	2.5
v. provide a compilation of egg collections and juvenile releases in 1998;	2.6
vi. provide a compilation of microtag, finclip and external tag releases by ICES Member Countries in 1998.	2.7
b) With respect to Atlantic salmon in the North-East Atlantic Commission area:	
i. describe the events of the 1998 fisheries and the status of the stocks;	3.1-3.4
ii. update the evaluation of the effects on stocks and homewater fisheries of the suspension of commercial fishing activity at Faroes since 1991;	3.5
iii. further develop the age-specific stock conservation limits for smaller stock units in the Commission area, where possible based upon individual river-based estimates;	3.7
iv. further develop methods to estimate the expected abundance of salmon for smaller stock units in the Commission area;	3.6
v. provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits;	3.8
vi. provide an estimate of the by-catch of salmon post-smolts in pelagic fisheries;	3.9
vii. identify relevant data deficiencies, monitoring needs and research requirements.	3.10
c) With respect to Atlantic salmon in the North American Commission area:	
i. describe the events of the 1998 fisheries and the status of the stocks;	4.1 & 4.2
ii. update the evaluation of the effects on US and Canadian stocks and fisheries of management measures implemented after 1991 in the Canadian commercial salmon fisheries;	4.3
iii. update age-specific stock conservation limits based on new information as available;	4.4
iv. provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits;	4.5
v. identify relevant data deficiencies, monitoring needs and research requirements.	4.6
d) With respect to Atlantic salmon in the West Greenland Commission area:	
i. describe the events of the 1998 fisheries and the status of the stocks;	5.1 & 5.2

ii. evaluate the effects on European and North American stocks of the West Greenlandic management measures since 1993;	5.3
iii. provide a detailed explanation of any changes to the model used to provide catch advice and of the impacts of any changes to the model on the calculated quota;	5.4
iv. provide age-specific stock conservation limits (spawning targets) for all stocks occurring in the Commission area based on best available information;	5.5
v. provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits;	5.6
vi. identify relevant data deficiencies and research requirements;	5.7
vii. comment on the report of Workshop on Peer Review of ICES Salmon Model <i>or in the absence of a Workshop</i> , examine critically the model used to provide catch advice, looking at all the assumptions, and comment on the confidence limits on the output from the model.	5.8

The Working Group considered 44 Working Documents submitted by participants (Appendix 1); other references cited in the report are given in Appendix 2.

A full address list for the participants is provided in Appendix 3.

2 ATLANTIC SALMON IN THE NORTH ATLANTIC AREA

2.1 Catches of North Atlantic Salmon

2.1.1 Nominal catches of salmon

Total nominal catches of salmon reported by country in all fisheries for 1960–98 are given in Table 2.1.1.1, and nominal catches in homewater fisheries, divided into size or age categories where such data are available, are given in Table 2.1.1.2. Catch statistics in the North Atlantic also include fish farm escapees and, in some north-east Atlantic countries, ranched fish (see Section 3).

The Icelandic catches are presented under two separate categories; wild and ranched. Iceland is the only North Atlantic country where large scale ranching takes place and where the intent is to harvest all returns at the release site. While ranching does occur in other countries it is on a much smaller scale than in Iceland, some are experimental operations and at others harvesting does not occur solely at the release site. As such, the ranched component in these countries has been left in the nominal catches.

Figure 2.1.1.1 shows the nominal catch data grouped by the following areas: ‘Scandinavia and Russia’ (including Denmark, Finland, Iceland, Norway, Russia and Sweden); ‘Southern Europe’ (including France, Ireland, UK (England and Wales), UK (Northern Ireland) and UK (Scotland)); and ‘North America’ (including Canada, USA and St Pierre et Miquelon); and ‘Greenland and Faroes’.

The updated total nominal catch for 1997 of 2,377 t is 755 t less than the total for 1996 of 3,132 t. While the 1998 catches in most countries remain below the previous 5-year and 10-year averages, about 50% of the countries reported an increase in catch compared to the final 1997 values. Figures for 1998 (2,401 t) are provisional, but the final total is likely to exceed the 1997 value.

The lack of information on fishing effort presents major difficulties in interpreting catch data for any one year and also in comparing catches in different years. However, it is clear that management plans in most countries have decreased fishing effort in recent years.

Reported nominal catches for several countries by number and weight are summarised in Table 2.1.1.3. As in Tables 2.1.1.1 and 2.1.1.2, catches in some countries include both wild and reared salmon (excluding ranched fish from Iceland) and fish farm escapees and the figures for 1998 are provisional. Different countries use different methods to partition their catches by sea-age class. These methods are described in the footnotes to Table 2.1.1.3. The composition of catches in different areas is discussed in more detail in Sections 3, 4 and 5.

2.1.2 Catch and release

The practice of catch and release (often termed hook and release) in rod (recreational) fisheries has been used as a conservation measure for large salmon in some areas of Canada and USA since 1984. Recent declines in salmon abundance in the North Atlantic has resulted in an increased use of this management option. The nominal catches presented in Section 2.1 are comprised of fish which have been caught and retained and do not include catch-and-release salmon. Table 2.1.2.1 presents catch-and-release information from 1991 for those countries which have records. Catch-and-release may be being practised in other countries while not being formally recorded. There are large differences in the percentage of the total rod catch that is released among countries ranging, in recent years, from less than 10% in Iceland to 100% in the USA, reflecting the varying management practices among these countries.

2.1.3 Unreported catches

Unreported catches by year and Commission Area are presented in Table 2.1.3.1. While comparisons of the 1998 unreported catch can be compared to previous values, it must be remembered that these figures are at best guess-estimates, and that the methods used to arrive at these figures have varied both within and among countries. Consequently, these figures should be interpreted with caution. A discussion of the methods used to evaluate the unreported catches is provided in Section 13 of the 1996 report (ICES 1996/Assess:11). A description of the methods used in Canada to evaluate unreported catches from 1997 onwards is presented in Section 4.1.2 of the 1998 report (ICES 1998/ACFM:15).

The total unreported catch in NASCO areas in 1998 was estimated to be 1210 t. Estimates were derived for the North American (91 t) and West Greenland (11 t) Commission Areas and for two sub-groupings, Scandinavia and Russia

(504 t) and Southern Europe (604 t), within the North East Atlantic Commission Area. Figure 2.1.3.1 shows that the unreported catch has remained a relatively constant proportion (30%) of the total catch since 1987. No data for the combined three Commission Areas is available prior to 1987.

No data were available on fishing for salmon in international waters in the Norwegian Sea or on vessels landing catches from this area in the 1997/1998 season. Very few surveillance flights were reported to have been undertaken by the Icelandic and Norwegian Coastguards over the winter period when fishing for salmon would be most likely to occur. Furthermore, these flights were associated primarily with the pelagic fisheries in the area rather than possible salmon fisheries.

2.2 Farming and Sea Ranching of Atlantic Salmon

2.2.1 Production of farmed Atlantic salmon

The worldwide production of farmed Atlantic salmon in 1998 was 710,342 t (Table 2.2.1.1 and Figure 2.2.1.1). This was the highest production in the history of the farming industry and represented a further 12% increase compared to 1997 (634,418 t) and a 50% increase on the 1993-97 average (475,032 t). The worldwide production of farmed Atlantic salmon in 1998 was over 295 times the nominal catch of Atlantic salmon in the North Atlantic.

The production of farmed Atlantic salmon in the North Atlantic area in 1998 was 538,011 t, which was a further 7% increase compared to 1997 (501,067 t) and a 37% increase on the 1993-97 average (391,627 t). The countries with the largest production were Norway and Scotland, which accounted for 64% and 21% of the total respectively. Proportional increases in production in the other seven countries were limited to between 0% and 4%.

In areas other than the North Atlantic, the production of farmed Atlantic salmon in 1998 was 172,331 t, 24% of the world production of farmed Atlantic salmon. As in the North Atlantic, production has increased throughout the time series. However, the current rate of increase in these countries is greater than that in the North Atlantic countries, the 1998 figure showing an increase of 29% compared to 1997 (133,351 t) and a 107% increase on the 1993-97 average (83,406 t). The areas with the largest production were Chile and the West Coast of Canada, which accounted for 73% and 19% of the total respectively. Proportional increases in production in the other seven areas were limited to between less than 1% and 6%.

2.2.2 Production of ranched Atlantic salmon

Ranching has been defined as the production of salmon through smolt releases with the intent of harvesting the total population that returns to freshwater (harvesting may include collecting fish for broodstock) (ICES 1994/Assess:16). The total production of ranched Atlantic salmon in countries bordering the North Atlantic in 1998 was 47 t, 10 t lower than in 1997 (57 t) and the lowest value since 1987 (Table 2.2.2.1 and Figure 2.2.2.1). Production in Iceland continued to show a decrease, due to fewer ranching facilities operated, but still accounted for 72% of the total ranched production in 1998. Production at experimental facilities in Ireland, UK(N. Ireland) and Norway has remained low. Production in Ireland includes catches in net, trap and rod fisheries. Icelandic catches, on the other hand, are entirely from estuarine and freshwater traps at the ranching stations.

2.3 Evaluation of Non-Catch Fishing Mortality for all Atlantic Salmon Gear

Fishing mortalities generated directly or indirectly by fishing but not included in recorded catches are referred to as non-catch fishing mortality. This type of mortality occurs as a result of various types of fishing gears that are used to capture salmon. Commercial fishing reportedly dates back to the 12th century and typically involves nets, traps and weirs whereby salmon are enmeshed, encircled or actively or passively swim into the device where they are captured. Nets may be stationary (often referred to as fixed engines), portable, drifted, thrown (cast) or used to dip salmon. Salmon are also taken commercially by long line, hand line (hook and line), and rod and line using natural or artificial baits or lures; these types of gears are currently more typically used in recreational or sport fisheries for salmon. As a result of the various types of fishing gear utilized to catch salmon in marine and freshwater areas of the North Atlantic, non-catch fishing mortality is extremely variable. Some of the factors known to contribute to variation in non-catch fishing mortality within and among fisheries include gear type, mesh type, duration of time that the gear is fished or set, gear selectivity, fish size and state of maturity, weather conditions and the care used in releasing fish which are not retained.

No new data or quantitative estimates of non-catch fishing mortality were available in 1999, although information relating to six sources of non-catch mortality was presented to the Working Group in 1979 (ICES 1981) and another

source was extensively reviewed in 1998 (ICES 1998/ACFM:15). The following sources of non-catch fishing mortality for Atlantic salmon gear are known to occur throughout the North Atlantic.

1. *Predation mortality* is caused by salmon caught in various types of fishing gear that are subsequently removed, eaten, lost, or released from the gear (or badly damaged) by the activity of seals, otters, other species of fish, gulls or other predators.

Predation mortality is known to take place where salmon fishing and salmon predators occur in the same localities. The magnitude of such mortality is influenced by the abundance of predators, the method of fishing used and other factors such as the frequency of gear inspection and removal of the catch. Thus, no universally applicable estimate of predation mortality is available for the North Atlantic. Predation mortality is not limited to salmon caught in commercial fishing gear; it may also occur in recreational fisheries, as a result of salmon that escape or are voluntarily released in a weakened physical condition. While predation mortality is normally thought to be low in commercial fisheries, anecdotal evidence obtained from Labrador in 1997 indicated that predation mortality may have been in the neighborhood of 50% of the landings in that fishery for that year.

2. *Dropout mortality* refers to fish caught and killed by the gear but lost prior to hauling the net.

Dropout mortality does not apply to many of the currently operating fisheries for salmon, since the methods and types of gear used are not immediately lethal to the fish. Observations of dropout losses from research vessel fishing with drift-nets at West Greenland in 1979 provided an estimate of 2-4% of the catch, while limited available evidence at that time suggested that dropout losses in gill-net fisheries in homewaters were similarly small.

3. *Haul-back mortality* refers to fish caught and killed by the gear but lost as a result of hauling back.

As with dropout mortality, haul-back mortality does not apply to many of the currently operating fisheries for salmon, since the fishing methods and gear used are not immediately lethal to the fish. Previous estimates of haul-back mortalities in gill-net fisheries ranged from 2-4% in West Greenland and 1-2% for commercial fisheries in Canada and homewater fisheries in the UK and Norway (ICES 1981). The types of fishing gears that were important sources of haul-back mortality are no longer extensively used in the North Atlantic.

4. *Escapement mortality* is caused when fish encounter and are temporarily caught by the gear, escape (or are intentionally released) from it or pass immediately through the gear but die later from various injuries or stress from the "encounter," or from increased predation due to their greater vulnerability to various predators.

Previous estimates of escapement mortality in commercial fisheries in West Greenland ranged from 5-15% of the recorded catch (ICES 1981). Escapement mortality in commercial salmon fisheries in homewaters is expected to be lower than at West Greenland because the fish exploited by them are approaching maturity and are physically and physiologically hardier. Escapement mortality in homewater recreational fisheries is considered to be lower than that for homewater commercial fisheries, due to the differences in the various types of gear used and how and when they are operated.

5. *Discard mortality* occurs when fish that are caught are discarded (dead or alive) and not included in the reported catches.

Discard losses are assumed to occur in all commercial fisheries for Atlantic salmon, although losses of this nature are likely to be small in most existing fisheries. Estimates of discard mortality in the Faroes fishery in 1983-84 ranged from 5-15% of the total catch and up to 80% for those fish that were discarded. In 1980 the Working Group concluded that its magnitude in homewaters was negligible (ICES 1981). The recent shift to catch and release angling in many homewater fisheries has resulted in a similar type of potential "discard" mortality which is discussed in greater detail below.

6. *Catch and release mortality* (often termed hook and release) occurs in recreational angling fisheries as a result of salmon that are caught and released, either voluntarily or as a result of mandatory requirements to do so.

Most studies to date have indicated that catch and release angling and associated handling results in mortalities of 0-10%, although at water temperatures of 20°C, and especially above 23°C, mortality can increase to much higher levels as temperatures continue to rise. However, at these higher water temperatures, the magnitude of rod catches also tends to decline very rapidly. Other factors may also increase mortality associated with catch and release, such as how long salmon have been in freshwater prior to being angled, various water quality parameters (including levels and flows) and

the care used by anglers when releasing hooked fish. Although more than 80,000 salmon were estimated to have been caught and released in 1998 (Table 2.1.2.1), the Working Group was unable to apply a general estimate of mortality due to a lack of information concerning the magnitude and extent of catch and release angling in many countries and the varying management practices in effect throughout the North Atlantic.

7. *Unreported catch* includes local sales, salmon eaten by fishermen or sold directly to the consumer, by-catch of salmon taken in gear not licensed to harvest salmon, and catches not otherwise recorded in official catch statistics.

The Working Group has provided annual estimates of unreported catches for all Commission areas of the North Atlantic since 1986 (Table 2.1.3.1).

2.4 Significant Developments towards Management of Salmon

2.4.1 Atlantic salmon post-smolt nurseries in the Northwest Atlantic

The Working Group considered research on the early marine life history of Atlantic salmon and considered how this new information may improve the procedures used to estimate pre-fishery abundance of the two seawinter stock component. The abundance forecast is a multiple regression model that uses a sea surface temperature index and a spawning stock size index to predict abundance in the current fishery year. The relationship between spawning stock and recruitment is direct, but the underlying factors related to the environmental factors are not well understood. The return of salmon from the ocean phase is affected by survival at sea and maturation at the end of the first winter which sends part of the cohort to natal rivers to spawn as grilse. The winter environmental signal has been hypothesized to be related to migration patterns and their effect on maturation variation (Friedland *et al.* 1998b). Post-smolt survival factors are equally difficult to assess due the difficulties in capturing and studying post-smolts.

Recent investigations in the Northeast Atlantic suggest that spring temperature conditions may be important to post-smolt survival, which supports a range of possible mechanisms affecting feeding, growth, and predation (Friedland *et al.* 1998a). These investigations have been extended by the examination of post-smolt growth for a stock in the area which shows that growth during the post-smolt year is correlated with the thermal conditions (Friedland *et al.*, in press, b). Similar associations have not been shown for North American stocks, possibly due to the nature of the distribution of the post-smolt nursery area along the Atlantic coast of Canada and the United States. Reports of inshore nursery areas (Dutil and Coutu, 1988) are in stark contrast to the ocean distributions of post-smolts reported in Europe. Using scale growth signals, Friedland *et al.* (1999) suggests that the North American post-smolt nursery area shifts in location annually and may include both offshore and estuarine waters. Considering the growth and catch rates for the three collection years, the first year, 1982, clearly supported higher growth and abundance in the Gulf of St Lawrence. The following years, 1983 and 1984, support slower growth and lower local abundance.

The Working Group considered temperature and chlorophyll abundance data as indicators of the nursery habitat suitability for the same years. From the analysis, 1982 was cooler in the Gulf during summer than the other years (Figure 2.4.1), suggesting these conditions either favor growth or are related to other factors that co-vary with growth. In addition, chlorophyll abundance in spring, which was taken as an indicator of likely recruitment success of the forage base, showed gradients between the Gulf and other areas. This preliminary work suggests optimal thermal conditions for post-smolts and production conditions for forage species may define nursery areas.

2.4.2 Migration of kelts in relation to sea water temperatures in Newfoundland

Data storage tags (DST) manufactured by Kiwi Inc. were applied to 139 Atlantic salmon kelts at enumeration facilities on Western Arm Brook, Humber, Campbellton and Highlands rivers, Newfoundland. In total, 12 of these Kiwi DSTs were subsequently recaptured and water temperatures downloaded. Control DSTs for verification purposes were applied to kelts held in a freshwater fluvium and indicated that water temperatures recorded by the DSTs were accurate.

Results from 11 recaptured tags indicated differences between rivers and among fish within a river (Figure. 2.4.2.1). Water temperature profiles are useful for indicating water temperatures encountered by salmon in freshwater and in the sea and may prove useful for determining temperature preferences. This information is important for marine climate change models and water temperature protocols for opening/closing angling fisheries in freshwater due to high water temperatures. Unlike some Pacific salmon no diurnal movements could be inferred. Salmon spent most of their time in water from 4.7 to 16.8° C.

2.4.3 Influence of release location of hatchery smolts on location of return as adults

Data from 401 recaptures of 56,960 Carlin-tagged reared smolts released between 1989 and 1997 in the River Dalälven (Bothnian Sea, Baltic) indicated that small distances between release sites effected differences in upstream migration patterns. Smolts were produced in and released directly from two hatcheries situated some 700 meters apart. In-river recovery rates of spawners recovered at a fishway located 800 m upriver of the most upriver hatchery were significantly higher for fish originating from the upriver station than those originating at the station 700m further down river. Salmon observed jumping at the outlet of the lowest station just prior to spawning suggested that hatchery return rates for the two stations could be equal. In that case, the difference in recovery rates at the fishway might be considered a proportionate measure of the stray rate effected by a distance of 700 m.

2.4.4 Relationships between biomass of Norwegian spring spawning herring and survival of Atlantic salmon

Post-smolts of Atlantic salmon from large areas of Europe have been observed in oceanic areas in the Norwegian Sea a few weeks and months after leaving their home rivers (Holm *et al.* 1998). In this area the distribution of Norwegian spring spawning herring (NSSH) and mackerel overlaps with salmon post-smolts in space and time (Holst *et al.* 1996). Post-smolts of Atlantic salmon may compete for food and space with other marine fish species. Herring larvae may be important food for post-smolts in coastal areas, but adult herring may be competitors in the ocean. The biomass of NSSH has increased considerably in recent years, and at the same time marine survival of Atlantic salmon stocks in the northeast Atlantic have declined. Thus it is reasonable to ask if herring affect growth and survival of post-smolt salmon.

Spawning biomass of NSSH and recapture rates of salmon tagged as smolts in the River Figgjo, southeast Norway, were inversely related (Figure 2.4.4.1). This supports the hypothesis that the presence of large numbers of Norwegian spring spawning herring in the Norwegian Sea may contribute to increased mortality of salmon in the ocean.

Many factors can affect survival of salmon in the marine environment, abiotic as well as biotic, and the interaction between them are little known. Species interaction may occur at several levels, and in the present case it may be asked if salmon post-smolts and herring compete for food. It is recommended that this should be tested.

2.4.5 Description of marine growth checks observed on the scales of salmon returning to Scottish homewaters in 1997

Samples of scales were routinely collected and examined from salmon caught in a number of fisheries throughout Scotland in 1997. Scales from adult recaptures in Scottish homewaters of North Esk salmon tagged as emigrating smolts were also analysed.

Substantial proportions of these scales exhibited summer checks (Table 2.4.5.1). Such summer checks are recognised as a number of successive narrowly spaced circuli occurring within a period of otherwise more widely-spaced circuli. Evidence that checks were not misclassified winter annuli is provided by the observation that the incidence of validated summer checks from scale samples taken from the North Esk recapture data set was within the range observed in the fisheries examined throughout Scotland.

For both 1SW and 2SW salmon, the incidence of summer checks in 1997 was outside the 95% confidence limits for the historical data sets examined.

All summer checks occurred during the first marine growing season in 1SW salmon or during the second marine growing season in 2SW salmon indicating that the checks were laid down in the same calendar year (1996) in both sea age groups. The incidence of summer checks in 2SW salmon was significantly less than in 1SW salmon. Furthermore, the incidence of summer checks varied significantly among months of capture for 1SW, although not for 2SW returns. In contrast, the position of the checks on the scales was estimated to have been the same across all groups.

The incidence of checks observed in maturing salmon returning to the Scottish coast in 1997 was the highest on record. While no significant link was shown with either growth or survival these observations further focus attention on the marine phase of the salmon's life cycle and on changes in the marine environment that may have an impact upon growth and survival.

2.4.6 Potential impact of seal and seabird predation on salmon in the Northwest Atlantic

Although declining salmon numbers in eastern North America are statistically associated with increasing harp seal populations, it cannot presently be determined whether predation by seals and sea birds is a cause of the declines in North American salmon returns. For such a cause-and-effect relation to be plausible, it must be shown that seals or other predators can account for a substantial fraction of salmon mortality at sea, and that such predation mortality could have increased.

Only nine records of seal (among a total of 5,680 grey, harbour and harp) and one record of seabird (other than gannet) predation on Atlantic salmon are available from marine diet studies in eastern Canada. Four of the seal records may, however, been of salmon taken from nets. Of the six remaining records, two are for grey seals, two are for harp seals, one is for a harbour seal and one is for a common murre. Three of these records are based on otoliths, the growth characteristics of which yielded unexpected calculated fish lengths for the time of year of capture, i.e., length calculations or species identification are erroneous. The remaining six records were used to derive consumption rate estimates.

Working Group reviewed a model which estimated numbers of smolts leaving North American rivers, daily numbers alive as post-smolts, salmon biomass, and vulnerability windows (size and age at which salmon are susceptible) to predation by estimated seal populations and potential seabird predators (inc. kittiwakes, fulmars, murre, shearwaters, gulls, and gannets). Estimates of salmon harvest based on calculated consumption rates and estimated seal populations were subject to numerous sources of error. Analysis suggests that predators could conceivably account for a substantial fraction, and possibly the majority, of salmon mortality at sea. Analyses also suggested that extremely large sample sizes would be required to detect and accurately characterize salmon predation.

Gannets are large seabirds which plunge-dive on pelagic prey, including post-smolts near the water's surface. Gannet diet is measured annually in August at Funk Island, off the northeast coast of Newfoundland. Salmon were infrequent in their diet, 1977-89, but increased in the 1990s to a peak of 6.4% of diet in 1993. The mean value, 1990-98, was 3.1%. Mean salmon consumption in August during the 1990s was estimated to be 3.6% of post-smolt biomass. Gannet diet is unknown for other months at Funk Island, and for other colonies in Newfoundland. If diet at Funk in August represents July-September diet at the two gannetries in northeast Newfoundland, then gannets could have consumed a mean of 13.7% of post-smolt biomass in the 1990s. Salmon have not been found in the diet of gannets in the Gulf of St. Lawrence where gannet populations are much larger than those of Newfoundland. Should these larger colonies participate even rarely in the harvest of post-smolts the loss of salmon biomass could be greater.

Populations of grey, harp, and hooded seals and of gannets and common murre have increased in eastern North America since the 1970s. Population trends for other seabird predators are unknown. The rising populations of seals and some seabirds, suggest that it is plausible that consumption by these predators may have contributed to declining returns of North American salmon. However, marine trophic interactions are complex and rising predator numbers do not necessarily depress prey populations.

2.4.7 Stock-recruitment relationships to define a conservation threshold and targets for Québec salmon rivers

Conservation thresholds for Atlantic salmon in Québec are being established using stock-recruitment (SR) analysis. The Ricker model (Ricker 1954) is appropriate for the species, which exhibits density dependence, at least during the freshwater phase.

Ricker's parameters (α , β) were replaced respectively with the mean maximal catch over many years (Copt), and the catch rate at Copt (h^*) (Schnute and Kronlund 1996). The catch rate is equal to $(Copt/(Sopt + Copt))$ where Sopt is the average spawner requirement needed to obtain Copt. A Bayesian approach was used to assess the uncertainties around the estimates, and to provide a risk analysis for suggested management actions (Walters and Ludwig 1994, Richards and Maguire 1998). Management plans favoring fixed escapements provide the best management and conservation results, providing the underlying assumptions are biologically realistic.

Québec salmon managers use two reference points: a conservation threshold and a management target. The new conservation thresholds will be defined by taking the MSY points determined from available SR relationships. These MSY points will initially be precautionarily fixed at 75% probability levels ($Sopt^{75\%}$). Management targets should be set at a higher level than the conservation threshold, depending on long-term management objectives.

SR relationships, associated reference points, and probability distributions, were calculated for six rivers (the Cascapédia, Dartmouth, Saint-Jean, York, Matane and de la Trinité, Figures 2.4.7.1 and 2.4.7.2) for which good data were available. To export the reference points to other rivers for which data were more limited, a measure of eggs/unit of production (UP) or eggs/m² which corresponded to the conservation threshold, was used (see below). This permits comparisons among different rivers.

Habitat suitability indices (HSI) (Terrell *et al.* 1995) were derived to classify river production units. These related parr densities with physical parameters (substrate, type of flow, river width, and a length of the growing season factor for different geographic areas (Power 1981)). HSIs were combined with basin wide habitat maps to generate estimates of Units of Production (UP). The HSI method is believed to be the most accurate approach, especially for rivers on the North Shore of the Gulf of St. Lawrence. An alternate way of evaluating production units consists in simply determining the wetted area accessible to the salmon.

Two regressions were derived correlating either UP, $Y=1.67*UP$, $r^2=0.89$, or wetted areas $Y=1.04*m^2$, $r^2=0.96$, with $Sopt^{75\%}$ values. The regression equations can be used to export $Sopt$ values to rivers where SR relationships are unavailable; the slope is the eggs/units value, and Y is the number of eggs needed to meet the conservation threshold.

Further analysis on transporting conservation limits across rivers is underway using Bayesian hierarchical analysis. The objectives are:

- 1) to confer more consistency in the overall data processing by working under a common Bayesian framework from the river-by-river analyses, to the transport across rivers;
- 2) to provide an evaluation of the uncertainty of the conservation limit when extrapolating the results obtained on the 6 index rivers to a new river where no SR data are available.

The Bayesian hierarchical analysis (Gelman *et al.* 1995) has been undertaken under the following model and hypotheses:

- after standardizing the SR data for river size (in UP), the 6 index rivers are considered as a set of exchangeable SR experiments;
- the likelihood is derived from the SR data using a Ricker model with lognormal process errors;
- each of the six index rivers has a common, prior lognormal probability distribution for $Sopt$ whose parameters are included in the analysis and thus considered as uncertain.

The output of this analysis is both an *a posteriori* probability distribution of $Sopt$ (eggs/UP) for each of the index rivers, and an *a posteriori* predictive probability distribution of $Sopt$ for a new river where no SR data are available. These probability distributions are presented in Figure 2.4.7.2. *A posteriori* distributions of $Sopt$ for the six index rivers are consistent among systems. The *a posteriori* predictive distribution of $Sopt$ for a new river falls among but has a greater dispersion than the dispersions observed for the index rivers. This reflects the absence of SR data for the new river.

2.4.8 Forecasting 1999 returns and assessment of alternative management options on the R. Scorff, Brittany

Since 1994, a scientific programme has been carried out on the Atlantic salmon population of the River Scorff (Southern Brittany, France). It aims at providing a better insight in the population dynamics of the species and developing methods to improve the assessment of stock status and management strategies. Smolt output and adult returns are estimated annually by trapping and mark/recapture techniques. At present the 1SW returns (1996, 1997, 1998) from three smolt cohorts (1995, 1996, 1997) have been observed. Information on the return rates as grilse can be derived from these data. By combining this information and the estimate of smolt output for 1998, a first attempt was made to forecast 1999 1SW returns. The analysis was undertaken under a Bayesian framework and followed two successive steps:

- a predictive posterior probability distribution of the 1SW return rate was built by means of a Bayesian hierarchical analysis which regarded the first 3 cohorts observed as a set of exchangeable experiments belonging to the same family of experiments (Gelman *et al.* 1995);

- the posterior predictive distribution of the 1SW return rates was then incorporated into a forecasting procedure to produce a predictive probability distribution of the 1999 1SW returns on the basis of the 1998 smolt output estimate.

At both steps, the uncertainty of the estimates of smolt production and adult returns (measurement errors) were taken into account.

The posterior predictive distribution of the 1SW return rate reflects the uncertainty on this parameter for a new year in the absence of data, given the observed data for the first 3 cohorts observed. It was obtained under the following model and hypotheses:

- adult return is a binomial process where each smolt has equal probability of coming back into its natal river, this probability representing the return rate which we attempt to make inferences on;
- prior knowledge is entered into the analysis by restricting prior probability distribution of the grilse return rate to conform to Beta distributions with a mode ranging from 0.025 to 0.2 and with a variance lower than that of a uniform distribution between 0 and 0.4.

A comparison of the posterior predictive distribution of the 1SW return rate with its prior probability distribution (Figure 2.4.8.1a) shows that the information provided by the data available led to a reduction in the uncertainty on this parameter, although a wide range of values are still seemingly probable. This uncertainty might be reduced in the future through additional data collected on forthcoming cohorts or by the introduction of covariables that can explain some the variability of the return rate, such as the mean size of the smolts.

The forecasting procedure used the same binomial model for adult returns from the smolt stage and the 1998 estimate of smolt production. Its output was a posterior predictive probability distribution for the 1999 grilse returns which showed a very wide 90% probability interval, from 130 to 1340 (Figure 2.4.8.1b). Although this result might appear rather disappointing, it must be emphasized that it certainly gives a more realistic view of our actual ability to predict returns one year in advance, compared to a point estimate, such as the most probable value.

Since the grilse represent about 90% of the returns in the Scorff R. and account for most of the egg deposition, further analyses were carried out to evaluate the probability that 1999 escapement will be above the conservation limit. Current knowledge on the ranges of the MSW returns and of the exploitation rates by sea age class, together with the current TAC based system of regulation of the exploitation (Porcher and Prévost 1996) were taken into account. The distribution of the egg deposition indicates that the probability of exceeding the conservation limit in 1999 is only 55% under current levels of exploitation and TAC (Figure 2.4.8.2a). Even if no fishery was allowed, the probability of falling below the conservation limit is still 30% (Figure 2.4.8.2b), mainly because of the rather poor smolt production in 1998.

In order to evaluate the effect of the current TAC based control of the exploitation, the probability distribution of the egg deposition obtained with or without TAC were compared. Both distributions could be exactly superimposed, suggesting that the TAC was not providing any protection against overexploitation (i.e. escapement below conservation limit). Even when considering an eventual doubling of the exploitation rates in 1999 relative to previous years (from [5%, 20%] to [10%, 40%]), the TAC, as currently set, was not reducing the probability of not achieving the conservation limit. An alternative and much more constraining management option was then evaluated. It delayed the opening of the fishing season to the 1st of July (from the present beginning of March), conditioned this opening on the number of returns observed up to this date and used a TAC approximately reduced by half from actual level. This alternative management option seemed to provide a better protection against overexploitation if the exploitation rates were to double in 1999.

Although preliminary the analyses suggest:

- current TAC levels used for regulating exploitation on the salmon rivers of Brittany might be too high and further evaluation of the performance of the management strategy currently applied is required;
- Bayesian statistics are of great interest for providing more realistic view of stock status or management strategies as they allow for a better description of the uncertainty in the assessment process. Further work in this field should be promoted, such as full risk analysis considering consequences of management options beyond the next year.

2.4.9 Salmon survey in the Labrador Sea in 1998

Experimental fishing was conducted by a Canadian research vessel fishing in the Labrador Sea in the fall of 1998. In total, nine stations were fished with fleets of monofilament gillnets of mesh size 77 mm, 89 mm, 102 mm, 115 mm, and 127 mm set to fish on the surface. In total, 38 salmon were caught, 24 of which were post-smolts and the remainder were 1SW salmon. Catch data and biological information from whole fish are:

Date	No. of fish	Life stage	Fork length (cm)	Whole weight (kg)
Sept 22	4	post-smolt	33 – 35	0.42 – 0.45
Sept 25	17	post-smolt	33 – 38	0.37 – 0.62
Sept 26	5	adult	60 – 71	2.99 – 3.78
Sept 27	6	adult	63 – 68	2.47 – 3.47

Catch rates ranged from 0 to 1.24 salmon per mile-hour of gear fished. Catch rates were lower than previously experienced by research vessels fishing in the same area in the late 1980s. These data will be added to the information base of research in the Labrador Sea. More research on post-smolt and adult salmon at sea is encouraged.

2.4.10 North American salmon recruitment, smolt indices, marine habitat and harp seal populations

A negative trend in recruitment of North American (NA) Atlantic salmon (*Salmo salar*) has persisted in spite of severely reduced commercial salmon fisheries. At the same time juvenile salmon production may have increased as a result of reduced home water exploitation. The Working Group reviewed a document that explored the relationship between recruitment of NA salmon, indices of smolt production based on fifteen standard electrofishing sites in the Miramichi River and either an index of salmon marine habitat (SHI) or annual population estimates of harp seals (*Phoca groenlandica*). Further analysis conducted at the meeting explored a weighted index of North American pre-smolts (see Section 4.2.1).

Over the range of years observed, 1972 to 1998, recruits (the summation of harvests and spawning escapements of NA salmon) were significantly negatively correlated with pre-smolt indices and harp seal populations for either one-sea-winter or two-sea-winter salmon (Figure 2.4.10). There was correlation among the predictive variables. Habitat in either February or March of the first sea-winter was positively correlated with pre-smolt indices. Habitat was positively correlated with the residuals of a simple recruitment model of logarithmic transformed pre-smolt indices for both one and two-sea-winter recruits. Harp seal populations were not significantly correlated with the residuals of the simple model of one-sea-winter recruits but were negatively correlated with the residuals of a simple model of two-sea-winter recruitment.

Models proposing the use of habitat and harp seals accounted for a high proportion of the variation in recruitment of the NA stock of salmon, had been reviewed previously (ICES 1998/ACFM:15). It was recommended that the appropriate recruitment model be further specified and supported (see Section 5.7.3). The development of a more comprehensive index of the relative change in marine predators of salmon in the Western North Atlantic Ocean is required. Also, verification of the assumption of direct proportionate production of smolts from the pre-smolt indices is required in order to isolate the life-stage underlying the negative relationship between pre-smolt abundance and adult recruitment.

The Working Group noted the high degree of correlation among variables and the paucity of evidence of the consumption of salmon by harp seals. These conditions prevent the derivation of specific conclusions concerning the nature of the relationships among recruits, habitat or the harp seal population. Because these variables cannot be controlled in the experimental sense, only additional years of data may provide the natural variation required for testing the validity of these models.

2.5 Framework for Stock Rebuilding Programs

The maintenance of self-sustaining stocks of salmon by means of targets or conservation limits requires that stock rebuilding programs are carried out when monitoring indicates that compliance with conservation values has not been achieved. It will be necessary to consider a range of issues before a decision is made to introduce a rebuilding program. It will also be necessary to decide which of a range of approaches to stock rebuilding is appropriate. In some cases, no action beyond increased vigilance during future monitoring cycles will be required. The flow-chart in Figure 2.5.1 has been constructed to provide a standard framework for decision making where targets or conservation levels are not

being met and stock rebuilding programs are being considered. Terms used in the flow-chart cells are underlined in the following text, in order to aid cross-referencing of the text and the chart.

The approach envisages that a conservation limit or target has been set previously as part of a stock management plan, and that the plan requires that the stock is monitored in order to assess compliance. If assessment shows that compliance has been achieved, the monitoring cycle can be resumed without further action. In the special case of a recovering stock for which interim targets have been set, compliance will be exceeded at each stage of recovery. In these circumstances it will be necessary to set new, greater conservation values as each step in the recovery process is achieved.

If a deficit is detected and the conservation value has not been met, it becomes necessary to consider the introduction of a stock rebuilding program. The first course will be to assess the validity of the value of the original conservation limit or target. Setting values is expected to be a particular problem in the early stages of any new management plan. Initial values will often be set in the absence of precise prior knowledge of the stock in question - some values will be set too high and some too low. If the original value is considered to be erroneous then the conservation value is reset at a new, lower level and the cycle of monitoring and assessment resumes.

If the original conservation value is considered to be valid, and the observed deficit is real, a more complex sequence of decisions must be made. In a well-established assessment program, an occasional failure to meet conservation limits might be judged acceptable. Indeed, frequency standards for the acceptance of occasional annual deficits may be a part of the assessment plan. Occasional non-compliance may also be acceptable for other reasons - perhaps on the basis of sustained, superior levels of performance in the past. Occasional failures will be most significant for stocks showing low levels of variation in total age at spawning. Where variation is greater, the effects of single-year deficits in egg deposition will be spread among several future spawning years. Considered in context, therefore, it may be possible to restrict action on a sporadic deficit to noting its occurrence, reserving other options for the future.

If instead an occasional failure of compliance is considered a significant deficit - perhaps because of the large magnitude of the deficit, or because it is part of a sequence of marginal events, or part of a developing trend - a further sequence of decisions must be made. In particular, it may be possible to establish causes or correlates of non-compliance by linking deficits or trends with specific changes in environmental or fishery variables. There are many possible effects of this kind, acting on a variety of scales, and they can be considered under a number of categorizations. Each of a suggested set of categories is discussed separately towards the end of this section.

If the causes, or candidate causes, of non-compliance can be identified, it may be possible to target action on the causes themselves as part of a stock rebuilding program. Alternatively, compensatory actions of other types, such as enhancement, can be directed at the appropriate level. If the cause of non-compliance is known but no remedy is available, it may be necessary to reset the conservation value before monitoring and assessment resumes. In the case of a deficit of indeterminate cause, the precautionary principle requires that a stock rebuilding program is initiated, in order to expedite recovery while further information on the underlying problem is sought. It will be necessary to monitor the response of the stock during any rebuilding program, as part of the continuing assessment cycle.

In some circumstances, a legal imperative may forbid the resetting of conservation values and a stock rebuilding program will be required even when the cause of the deficit is known to be irremediable. In the most unusual circumstances, where salmonids can no longer live in previously productive habitat, the conservation value may reset to zero. In this case, mitigation can be considered for temporary support of the stock while the problem is resolved. If the problem has no solution, self-sustaining salmon fisheries are lost, and put-and-take fisheries or fisheries on other species are the only options which remain.

As regards targeting a stock rebuilding program, it is suggested that consideration of causes and correlates of non-compliance centre on changes with time in four categories of effect. The proposed categories are climate, biological interactions, physical habitat and fisheries and each of these is considered separately below. It is important to note, however, that the categories are not totally discrete and that, in many cases, interactive effects among categories are expected to occur.

There are two primary steps in considering the relevance of any of the four categories in the context of particular instances of non-compliance. Firstly, it is necessary to establish the geographical scale of non-compliance by comparing the stock unit in question with other stocks. This context - whether the violation is local, or part of a regional, national or range-wide pattern - will direct attention to variables or issues operating on similar geographical scales. Secondly, it is necessary to determine at which stage of life the size of the stock is being restricted by unexpectedly low levels of performance. For example, low fry densities resulting from adequate spawning escapement will direct attention towards adverse factors acting in fresh water - during spawning, egg incubation, hatch or dispersal. Low adult return rates from adequate levels of smolt production will suggest that the limiting factor has operated at a later stage of life. It is

important to note that this general guidance is not completely secure. The salmon life-cycle is complex and factors acting at any stage of life have the potential to affect growth and survival later on. For example, variation in smolt size is likely to affect predation risk early in the marine phase.

Climatic variables are those that directly affect the conditions in which fish live and grow. Temperature and precipitation are the principle factors of concern. Temperature is of primary importance, both in fresh water and in the sea, since it is a direct determinant of growth and other related performance variables. In addition, brief episodes of high temperature prove lethal in fresh water and, in the sea, salmon demonstrate a strong preference for a relatively narrow temperature range and thus tend to limit their distribution. The second climatic variable of importance is precipitation which affects ground-water discharge, and therefore stream temperature, and stream-flow. Stream discharge affects pH values, it determines wash-out rates for eggs and wetted habitat area for juveniles, and allows access for adults moving upstream. Climatic variables are expected to have a strong affect on levels of compliance with conservation values. Although climatic variations are beyond management control, it may be possible to limit adverse effects by using compensatory management actions to alter variables in other categories of effect.

Biological interactions include a wide range of temporally variable effects relating to interactions with other species. These include the adverse effects on wild salmon of inter-specific competition in streams, introduction of non-native species, low abundance of prey species in fresh water and in the sea, excessive mortalities due to predation, and mortality due to outbreaks of disease or parasites, such as *Gyrodactylus salaris*. The category also includes interactions with other fish of the same species, because of the possible adverse effects of escapees from aquaculture on the productivity of wild salmon stocks and the negative effects of indiscriminate stocking from hatcheries. With the exception of aquaculture and hatchery effects, remedial action is not a realistic possibility for many interactive effects.

Physical habitat effects that vary among years or over decadal scales are likely to affect compliance with conservation values. All of the physical habitat effects that have the potential to affect production and survival of salmon exert their effects in fresh water. Many of these effects are attributable to the effects of non-fishery forms of land- and water management. They include siltation of spawning gravels following changes in land-use, channelization and destruction of stream habitat, stream enrichment through fertiliser run-off and sewage discharge. Impoundment works reduce habitat by drowning streams, and they alter temperature regimes. In-stream construction works may limit access to potential habitat. Because these effects are often caused by the activities of man, they are often open to direct remedy.

Fishery effects are dealt with extensively in the other parts of this Report. Fisheries are particularly likely to contribute to non-compliance with conservation values because they exploit adult fish towards the end of the life-cycle after other restrictions on stock size have had their effect. In addition, the effect of uniform fisheries on adult recruitment is variable since exploitation rate often rises when abundance is reduced. Fishery effort is inherently manageable. The fisheries are well-documented relative to the other factors affecting stock size. So, fishery regulation is likely to remain the most effective route towards ensuring compliance with conservation limits or targets. Management of the fisheries is also a practicable route towards managing compliance, because of the close association of the regulatory authorities with the various parties who benefit from exploiting the resource, and because of close association of both parties with those attempting to optimise production.

2.6 Compilation of Egg Collections and Juvenile Releases for 1998

2.6.1 Egg collections and juvenile releases for 1998

The Working Group compiled 1998 data summaries of artificially spawned eggs and egg and juvenile releases in Table 2.6.1.1. These data were provided to estimate the effects of egg collection on wild production and to characterize the overall scale of enhancement work by ICES member countries. Although all countries except Finland artificially spawn eggs to support enhancement activities, only eight countries reported summaries of artificially spawned egg numbers for 1998. Two countries (Canada and the United States) collect eggs from domestic/captive broodstock and/or captive sea run kelts in addition to collections from sea run fish. Where possible, the number of eggs collected from each of these sources is reported.

For most countries, the database has been expanded to include historical data from 1990 to 1997, and these data are summarized in Appendix 4. As data reporting becomes more complete for the pre-1998 period, this information can be used to describe temporal trends in enhancement activities.

2.7 Compilation of Tag Releases and Finclip Data by ICES Member Countries in 1998

2.7.1 Compilation of tag releases and finclip data for 1998

Data on releases of tagged and fin-clipped salmon in 1998 were provided by the Working Group and are compiled as a separate report (Annex to ICES CM 1999/ACFM:14). A summary of Atlantic salmon marking in 1998 is given in Table 2.7.1.1. Slightly over 2.59 million salmon were marked in 1998, a 14% decline from the 3.02 million fish marked in 1997. Primary marks are summarized by four types; Microtag, External Tag, Adipose Clip, and Other Visible Marks. Secondary marks (primarily adipose clips on microtagged fish) are also recorded. The Adipose clip was the most used primary mark (1.66 million), with microtags (0.70 million) the next most used primary mark. Microtag marking declined by 5% from 1997. Secondary marks (primarily adipose fin clips) were applied to 0.87 million fish. Most marks were applied to hatchery-origin juveniles (2.53 million), while 0.04 million wild juveniles and 0.02 million adults were marked.

Table 2.1.1.1 Nominal catch of SALMON by country (in tonnes round fresh weight), 1960-1998. (1998 figures include provisional data).

1. Includes estimates of some local sales, and, prior to 1984, by-catch.

2. Since 1991, there has only been a research fishery at Faroes.

In 1997 no fishery took place.

3. Includes catches made in the West Greenland area by Norway, Faroes, Sweden and Denmark in 1965-1975.

4. From 1994, includes increased reporting of rod catches.

5. Catch on River Foyle allocated 50% Ireland and 50% N. Ireland.

6. Before 1966, sea trout and sea charr included (5% of total).

7. Figures from 1991 onwards do not include catches taken in the recently developed recreational (rod) fishery. These will be included in next year's report.

8. Weights prior to 1990 are estimated from 1994 mean weight.

Weights from 1990 based on mean wt. from R. Asturias.

9. Not including angling catch (mainly 1SW).

10. Includes catches in Norwegian Sea by vessels from Denmark, Sweden, Germany, Norway and Finland.

11. Estimates refer to season ending in given year.

Table 2.1.1.2 Nominal catch of SALMON in homewaters by country (in tonnes round fresh weight), 1960-1998. (1998 figures include provisional data).
S = Salmon (2SW or MSW fish). G = Grilse (1SW fish). Sm = small. T = S + G or Lg + Sm

¹ MSW includes all sea ages >1, when this cannot be broken down.

Different methods are used to separate 1SW and MSW salmon in different countries:

- Scale reading: Faroe Islands, Finland (1996), France, Russia, UK (England and Wales), USA and West Greenland.
- Size (split weight/length): Canada (2.7 kg for nets; 63cm for rods), Finland up until 1995 (3 kg), Iceland (various splits used at different times and places), Norway (3 kg), UK (Scotland) (3 kg in some places and 3.7 kg in others). All countries except Scotland report no problems with using weight to categorise catches into sea age classes.

In Scotland, misclassification may be very high in some years.

In Norway, catches shown as 3SW refer to salmon of 3SW or greater.

Table 2.1.2.1 Numbers of fish caught and released in rod fisheries along with the % of the total rod catch (released + retained) for various countries in the North Atlantic, 1991-1998.

Year	Canada (1)				Iceland		Russia		UK(E&W) (2)		UK(Scot) (2)				USA

1. Figures for 1992 to 1996 are minimal estimates as not all areas have reported catch and release. The 1998 figure is provisional.

2. Figures for 1998 are provisional.

Table 2.1.3.1 Guess-estimates of unreported catches in tonnes within national EEZs in the North-East Atlantic, North America and West Greenland Commissions of NASCO, 1986-1998. In 1998, unreported catches in the North-East Atlantic have been split into two regions.

3 FISHERIES AND STOCKS IN THE NORTH-EAST ATLANTIC COMMISSION AREA

3.1 Fishing at the Faroes in 1997/1998 and 1998/1999

In the period 1991-98 inclusive the Faroese salmon quota was bought out. However, the Faroese Government continued sampling inside the 200 mile EEZ during most of the period (ICES 1997/Assess:10), including January-April, 1998. No buyout has been arranged for 1999 and the prospects for a salmon fishery in the coming 1999/2000 fishing season is unknown.

3.2 The Research Programme at the Faroes

3.2.1 Gear, effort and catch in the research fishery

The salmon long-liner M/S "Polarlaks" conducted a research fishery from January to early April 1998. Four separate trips were carried out with 31 sets fished which caught 5.8 t (1,763 salmon) including discards (Table 3.2.1.1). The catch rate (CPUE) in 1998 was 30 salmon per 1,000 hooks employed. This is below the range of 36 to 84 fish per 1,000 hooks for the fishery 1981 through 1995 (ICES 1996/Assess:11).

3.2.2 Composition of the research fishery catch

The length distribution of salmon in the Faroese area in the winter of 1998 is shown in Figure 3.2.2.1. The sea age was determined from previous age-at-length data (ICES 1996/Assess:11). As in previous fishing seasons, the 2SW salmon dominated (75%), 1SW (19%) and 3+SW (6%) were caught in lower proportions (Table 3.2.2.1).

The proportion of discards in the catch (i.e., salmon <60 cm) was 16.9% which is higher than the previously noted range of 1.8 to 15.6 (ICES 1996/Assess:11). However, the fishery only took place from January to April and not over the entire season as in previous years and it is known that the proportion of discards is higher in the early part (October-November) of the season.

3.2.3 Origin of the research fishery catch

Approximately 1000 scale samples were collected from salmon in 1998, but they have not been analysed. Therefore there is currently no available information on the proportion of escaped farmed salmon in the Faroese area.

In total, eight external tags were recovered in the 1998 sampling with "Polarlaks". Seven tags came from salmon which had originated in Norway and one tag originated from Sweden. Although 25 finclipped salmon were caught, none of these bore coded wire tags. Despite the small sample size, the recovery of tags is consistent with previously estimated proportions of tagged fish from other countries (ICES 1996/Assess:11).

3.3 Homewater Fisheries in the NEAC Area

3.3.1 Significant events in NEAC home-waters

A committee was appointed by the Norwegian Ministry of Environment to discuss and describe the causes of the decline of wild salmon in Norway and to propose measures to counter-act the decline. The report of this committee has recently been published and will be considered by government following public hearings.

While Iceland has had a general ban on fishing for salmon in the ocean, (with the exception of coastal fishery at five locations at the west coast), the rights to fish in these waters have now been permanently bought out by fishery associations in nearby rivers with the support from the Icelandic state. Consequently, practically all the fisheries in 1998 were carried out in freshwater.

The restrictive measures introduced in Ireland in 1996 to reduce fishing effort were also applied in 1998. Efforts continued in Ireland to comply with the recommendations of the Salmon Management Task Force which reported in 1996. A national carcass tagging scheme for salmon caught by commercial and recreational fisheries has been designed and proposed. Funding was obtained to install and operate fish counters on 22 rivers in Ireland for the purposes managing fisheries on a real time basis. These initiatives will be linked to a quota scheme which should come into effect within the next two years.

In Russia, significant changes occurred in the operation of the barrier fences at the Tuloma and Uмба Rivers where all salmon returning to these rivers were allowed to ascend to the spawning grounds. Therefore, only five barrier fences were operated commercially compared to 7 in the two previous years, and 10 in 1995.

A Swedish working group on the evaluation and further development of the status of the salmon populations on the West Coast was established in 1998.

In April 1999, new national measures were introduced in the UK (England and Wales) to protect early running MSW ("spring") salmon. Most nets and fixed engine fisheries will be closed until 31 May each year and anglers will be required to release all salmon caught before June 16. The measures will be reviewed after 5 years.

3.3.2 Gear

Changes in gear regulation were introduced in two countries within the NEAC Area. The ban on the use of bend nets along the Norwegian coast from Rogaland County to Troms County introduced in 1997 was again applied in 1998. In Iceland, the coastal gillnet fishery, which in recent years has accounted for only a very small percentage of the nominal catch, was permanently bought out prior to the beginning of the season.

3.3.3 Effort

The number of gear units licenced in several of the NEAC Area countries are shown in Table 3.3.3.1. This provides a relative assessment of effort. However, there is no indication from these data on the actual number of licences fished or the amount of time each licensee fished. In most cases shown, the number of net licences has declined compared to the previous 5- and 10-year means.

In 1998, the number of net fishing licences showed further decreases compared to 1997 in UK (England and Wales), UK (Scotland), Norway. In UK (Northern Ireland) all three netting methods showed a small increase in effort compared to 1997. In Ireland, the number of draft net licences issued increased while the number of drift net licences has remained constant over a number of years.

The number of rod licences showed no clear trend, in contrast to the general decline in licences issued to the net fisheries over the last decade. In Ireland, the number of salmon licences issued in 1998 shows an increase on 1997 and on the previous 5- and 10-year means. In Finland, although effort in 1998 was up on 1997 it was down on both the previous 5- and 10-year means. In France, rod effort was up on the previous 5 year mean but down on the 1997 value and on the previous 10-year mean.

In Ireland and UK (N. Ireland) weather conditions were poor in the June and July. Water levels in many rivers were exceptionally high.

3.3.4 Catches

NEAC area catches are presented in Table 3.3.4.1. Figure 3.3.4.1 shows the percentage change in the 1998 NEAC homewater catches relative to the previous 5-year (1993-97) and 10-year (1988-97) means. With the exception of Russia the 1998 catch in all countries showed substantial decreases compared to the previous 5- and 10-year means. This is believed to reflect reductions in fishing effort (Section 3.3.3) and reductions in stock (Section 3.4). The 1998 catch in Russia showed a small increase over the previous 5-year mean but was substantially less than the previous 10-year mean.

3.3.5 Catch per unit effort (CPUE)

CPUE data for the NEAC area are presented in Tables 3.3.5.1, 3.3.5.2 and 3.3.5.3. In the UK (England, Wales) and UK (Scotland), CPUE for net fisheries has decreased from the previous year. Route regression analysis showed a significant decreasing trend for UK (Scotland) net fisheries ($p = 0.996$) for the last 10 years (Table 3.3.5.4). No trend was detected for the UK (England and Wales) net fisheries ($p = 0.3$).

In Finland (River Näättämo), France and in UK (Northern Ireland) (River Bush) CPUE for rod fisheries increased in 1998 compared to 1997. However, CPUE of the River Teno (Finland) was slightly lower than in 1997. Catch per angler season (Finland, France) showed a significant increasing trend in the past 10 years (Table 3.3.5.4, $p = 0.06$) but not for Finland or N. Ireland ($p = 0.12$). Catch per angler season for rod fisheries in the Russian rivers of the White Sea basin showed a significant increase ($p = 0.001$), whereas that of the Barents Sea basin rivers decreased ($p = 0.997$).

3.3.6 Age composition of catches

The percentage of 1SW salmon in catches are presented in Table 3.3.6.1 and Figure 3.3.6.1 for those countries where a time series of data exist. The proportion of 1SW fish in the 1998 catches is presented as a percentage of the 1993-97 mean, and, where data are available, the 1988-97 mean. In Finland, France, Norway, Russia and UK (Scotland) the proportion of 1SW fish in the 1998 catch has increased relative to both long term indices. Compared to the previous 5-year mean, the proportion of the catch comprising 1SW fish in 1998 had increased in the UK (England and Wales), and decreased in Sweden.

3.3.7 Farmed and ranched salmon in catches

The contribution of wild, farm-origin and ranched salmon to national catches in the NEAC Area 1991-1998, is shown in Table 3.3.7.1. In 1998, farmed salmon continue to account for a relatively large proportion of the nominal catch in Norway (28%). Although no fishing was carried out in the Faroes in the 1996/1997 fishing season and no determination of origin of catches is yet available for the 1997/1998 fishing season, data from previous years suggest that there is a relatively high proportion of farmed salmon in this area as well.

In Norway, the incidence of farmed salmon in coastal fisheries in 1998 was estimated to be 45%, and in fjord fisheries the corresponding value was 43% (Table 3.3.7.2). These values are similar to those recorded in 1997. In 1998, the proportion of farmed salmon in rod catches was 8% whereas in broodstock samples the incidence was estimated to be 22% (Table 3.3.7.3). There was a large amount of variation around the mean values for both the rod fisheries and the broodstock collections among the various sampling localities.

In the River Teno (Finland and Norway), the incidence of farmed salmon during the fishing season in June-August has been low, varying mostly between 0.1 and 0.4%. However, some occasional sampling after the fishing season in September-October has resulted in much higher proportions of farmed fish, reaching the level of 30-50% (Table 3.3.7.4) indicating that the proportion of farmed fish in the spawning stock may be higher than reflected from the in-season samples. This is similar to the findings presented from other parts of Norway (Table 3.3.7.3).

In UK (Northern Ireland), only 0.20% of the reported catch comprised farmed salmon, a value similar to the previous two years (Table 3.3.7.5).

Inshore coastal catches of salmon in both UK (Northern Ireland) and Ireland are examined for escaped farmed salmon (Table 3.3.7.6). Data for both countries are presented together as they constitute a continuous part of the species' geographic range. Escaped farmed fish have been detected every year; the frequency being less than 1% in most years. The 1998 figures remain at this level.

A catch sampling programme in UK (Scotland) from 1981 to the present indicates that the incidence of farmed salmon in catches of fisheries around the country continues to decrease from their highest recorded levels around 1993 (Table 3.3.7.7).

There were no significant catches of farmed salmon reported from the other NEAC countries.

3.3.8 National origin of catches

In Sweden, it was estimated that 10% of the salmon catch in 1998 consisted of recaptures of tagged salmon which originated from Danish experimental releases at the islands of Møn and Bornholm. No other new information was made available to the Working Group.

3.3.9 Exploitation rates in homewater fisheries

Exploitation rates for 14 wild stocks and three mixed stocks are shown in Table 3.3.9.1. Exploitation rates increased in 1998 from those of 1997 for 12 stocks but decreased for four of the stocks where data were available. Compared to previous year exploitation rates increased for the rod catch in five rivers in UK (England and Wales) but decreased in two rivers. In the North Esk (UK Scotland) exploitation rates increased for 1SW but were the same for 2SW as the previous year. Exploitation rates increased for 1SW fish in the rod catch in River Ellidaar (Iceland) and in the net catch in River Lagan (Sweden) for both 1SW and 2SW fish. Of eight rivers reported for Russia, exploitation rates had decreased in seven from the 1997 fishing season. Route regression analysis shows that there was a significant downward trend for rivers flowing to the Barents Sea for both the past 10-year and 5-year periods and for the past 10-year period for the rivers flowing to the White Sea (Table 3.3.5.4). Route regression analysis also shows a significant

downward trend in exploitation rates for 2SW stocks in UK Scotland, Iceland, Norway and Sweden for the past 5-year period.

3.3.10 Summary of homewater fisheries in the NEAC area

Since the late 1980s there has been a declining trend in salmon catches in the NEAC area. This reflects attempts by many countries to reduce commercial fishing activities because of conservation needs. Other associated factors are lower stock levels and a reduction in the value of commercially caught salmon.

Provisional figures show an increase in salmon catch from 1997 to 1998 in most northern European countries (Iceland, Norway, Finland, Russia) and in Ireland, Spain and France. This increase is due mainly to increased grilse catches. In contrast, catches in UK and Sweden have decreased from the previous year. Proportions of 1SW salmon were generally above the 1997 values and the 10-year and 5-year means.

Farmed salmon continue to represent a large proportion of the coast, fjord and brood stock catches in Norway (22-45%), although the proportion has remained relatively stable over the past few years. The proportion of farmed fish is generally less than 1% in fisheries in UK, Ireland and Finland. Ranched fish comprise 40% of the salmon catch in Sweden and 20% in Iceland, whereas the proportion in other countries is generally less than 1%.

Commercial fishery effort continued to decrease in net fisheries in UK. CPUE of the commercial fishery in UK (Scotland) has decreased. In Finland and France, catch per angler season show an increasing trend. Similarly, CPUE of rod fisheries in the Russian rivers of the White Sea basin showed a significant increase, whereas that of the Barents Sea basin rivers has decreased.

3.4 Status of Stocks in the NEAC Area

3.4.1 Attainment of conservation limits

In order to provide a composite view for the NEAC area over the last 10 years (1989-98), escapement levels were examined for rivers where egg deposition can annually be equated to a conservation limit (CL). Data was available for 18 rivers in the NEAC area. Egg depositions were assessed on the basis of pooled 1SW and MSW spawners but future efforts will attempt to account for stock composition. Sixteen rivers, five from Russia, five from UK (England and Wales), three from France and one each from Ireland, UK (Northern Ireland), and UK (Scotland) had sufficient data to be included in the 10-year analysis (Table 3.4.1.1). (The River Dee, UK [England & Wales] was included even though there were only seven years of data). For each river, escapement was divided by its CL so that escapement status could be readily compared across rivers independent of various river CLs.

Of the 157 cells (year-by-river) 81 (52%) had escapement levels below the CL (Table 3.4.1.1). One river never attained its CL during the last ten years while three rivers were always above their CL. By ranking the rivers according to the mean rate of CL attainment, four categories were distinguished:

- five rivers in which egg deposition was mostly below CL (means of the river CL attainment rates of 0.44 to 0.78). Within this group, only 10% of year-by-river cells had depositions in excess of the CL, 36% of cells had an escapement lower than half of the CL;
- five rivers in which egg deposition fluctuated around CL (means of the CL attainment rates of: 0.94 to 1.17). Forty-seven percent of the river-by-year cells had deposition in excess of the CL. In 9% of the cells escapement was more than twice the CL while in 6 % of the cases, deposition was less than 50% of the CL. As a result, escapement varied between one-half and twice the CL 85% of the time;
- four rivers in which egg deposition was mostly in excess their CL (means of the CL attainment rates of 1.44 to 1.89). For these rivers, 73% of the river-by-year cells had depositions in excess of the CL, and of these 38% had levels in excess of twice the CL. No cells had less than one-half of the CL;
- two rivers in which deposition was well above CL (means of the CL attainment rates of 2.48 and 2.88). These rivers never fell below CL during the last 10 years and in 80% of the cases, egg deposition exceeded twice the CL.

On the basis of change in CL values over the last 10 years, the 16 rivers examined could be classified into two groups (Figure 3.4.1.1):

- nine rivers showing a decreasing trend ($p < 0.01$, route regression);
- seven rivers with no trend around their mean ($p = 0.12$, route regression).

No rivers had an increasing trend.

In combination the two categories indicate that:

- rivers having the lowest and the highest egg depositions are stable (4/7) or decreasing (3/7);
- rivers with escapement levels intermediate to the two extremes (fluctuating around the CL or mostly above CL) are mainly decreasing (6/9).

For all rivers, the period 1994-97 had the poorest egg depositions with 10 to 12 rivers below their CL in each year. In contrast, 1989, 1993 and 1998 tended to be the most favourable years with 9 to 10 rivers out of the 16 being in excess of the CL. In 1998, depositions in 12 of the 16 rivers improved over those of 1997.

No overall conclusion could be drawn at a regional scale within the NEAC area. This was because of the absence of consistent patterns within each country or region represented in the set of rivers, the small number of rivers with data available and the absence of information for rivers in Scandinavia.

In summary, the rivers of the NEAC area show a broad range of situations in term of escapement levels from rivers that never reached their CL over the last 10 years to rivers which were consistently well above their CL. This variation in status is evident at an even lower geographical scale (region or country). In total, low CL attainment rates and their slope during the last 10 years is cause for concern:

- no tendency to recover is observed for the stock at low escapement levels;
- in most instances, stocks having average egg deposition levels equal or greater than their CL tend to exhibit some deterioration in their escapement; at best they just fluctuate around their mean.

Within this context, 1998 was a relatively good year and showed an improvement in most cases over 1997 (Figure 3.4.1.2). Further efforts are to be made to obtain estimates of egg deposition broken down by sea-age classes of spawners (1SW vs MSW).

3.4.2 Measures of juvenile abundance

Smolt counts or estimates of juvenile abundance are available for 17 rivers (Table 3.4.2.1). About half of the values for smolt counts in 1998 are higher than in the previous year, whereas most of the values are higher than the 5-year means. The values for rivers Burrishoole (Ireland) and Bush (UK, Northern Ireland) were well above the earlier levels, whereas those for the Scottish rivers were lower than before. The Scandinavian rivers showed both higher and lower smolt abundances than in the previous year. Two groups were roughly identified from plots of the data. Regression analysis revealed a significant positive trend for the past five years for the group that comprised the rivers Halselva, Imsa (Norway), Hogvadsån (Sweden), Oir (France), Burrishoole and Bush (Table 3.4.2.2.). No trend was detected for the last 10 years. A significant 10-year decreasing trend was detected for the other group (rivers Orkla (Norway), Ellidaar (Iceland), North Esk, Girnock and Baddoch (UK, Scotland)), whereas no trend was detected for the past 5-year period.

Estimates of juvenile salmon (fry and parr) abundance in 1998 were at the same level as in 1997 in the River Teno (Finland and Norway) and its two tributaries but lower than the 5-year means. The fry abundance estimate for the River Bush was well below the level of 1997 and the 5-year mean. In UK (Northern Ireland), record high flow levels during the spring and throughout the summer of 1998 are believed to have contributed to much lower than normal survival of juvenile salmon (and trout) in the R. Bush and raise concerns about the knock-on effects on smolt runs in years 2000 and 2001.

Preliminary analyses of long-term trends in juvenile survey data in three rivers in the UK (England and Wales) indicated significant declining trends at five of the ten sites and a significant increasing trend at only one site.

3.4.3 Measures of adult returns back to the rivers

In order to depict temporal trends in the adult returns into the rivers of the NEAC area, an analysis was carried out using adult counts provided in Table 3.4.3.1. These data of adult returns are intermediate between recruitment back to the coast and spawning escapement, because in most cases the counting facilities are located below riverine fisheries. MSW and 1SW fish are pooled. In the case of the Girnock and the Baddoch burns, two small tributaries of the Dee (Scotland) where fish enter at spawning time, only the females were taken into account. These were considered to better reflect overall abundance due to the difference between both sexes in their behaviour relative to the trapping facilities at the time of spawning.

In order to provide the widest possible geographical view, only the data for the last ten years (1989-98) were considered. All rivers with at least seven years of data out of ten were included in the analysis. In order to look only at temporal trends, independent stock size, each series was divided by its mean. As a result, all the transformed series had a mean = 1. Therefore any data lower or greater than 1 corresponds to returns lower or greater than the last 10 year average respectively. Cluster analysis (Ascending Hierarchical Classification based on an inertia criteria with a chi-square distance) was used to help define groups of rivers showing common features in temporal trends. This method provides a hierarchy of classes which is of interest when trying to subdivide categories into sub-categories (Lebart *et al.* 1984). Inertia criteria take into account not only the distance between elements to be aggregated but also their size, thus avoiding chain effects i.e., when groups of categories are not identified due to overlap with smaller groups or single categories. Chi-square is the separation measure used when looking at the profiles i.e., comparing relative importance of series of positive numbers.

Two broad categories can be distinguished at first (Figure 3.4.3.1 and Figure 3.4.3.2):

- 19 rivers (58%) which had decreasing salmon returns over time whereas 13 (39%) showed no trend;
- one river out of 33 which tended to increase (although no data was available for it for the last 2 years).

The broad category of decreasing rivers could be split into four subgroups:

- The first subgroup (five rivers) showed a continuous trend over the study period.

The other three showed a two-step pattern i.e. fluctuations around values higher than the mean, followed by fluctuations around values lower than the mean. The years of transition between these two steps were lagged between the 3 subgroups:

- The second subgroup (5 rivers) showed a strong decrease at the beginning of the period analysed (1989-91) with no recovery thereafter;
- The third subgroup (5 rivers) had a drop from 1992 to 1994;
- The last subgroup (4 rivers) was affected by an abrupt change between 1994 and 1995.

Within the category of rivers showing no trend over time two subgroups could be identified: one subgroup of these (nine rivers) reflected inconsistent variations between rivers whereas the other (four rivers) was characterised by a notable improvement in 1998 over 1997.

In terms of geographical patterns (Figure 3.4.3.3), a partition of the 33 rivers into two broad regions, north-east (Scandinavian countries and Russia, 14 rivers) and south-west (UK, Ireland and France, 19 rivers) revealed differences in returns over the last 10 years. In the north-east region, most rivers showed a decline (10/14, 71%) whereas in the south-west region the split between rivers decreasing or with no trend was about balanced (9 declining against 10 stable or showing some improvement).

The pooling of MSW and 1SW fish in the data sets available was a major limitation to the analyses. Each sea-age represents alternative life history strategies which potentially maximise stock survival (e.g., coping with changes of the environment). As illustrated by the apparent decline in MSW stocks relative to grilse stocks, there is little reason for sea-age components to have same pattern of return over time. More insight into the trends in adult returns over time could be provided if the data were available for MSW and 1SW salmon separately.

In summary, it must be emphasised that adult returns to index rivers within the NEAC area have been declining or showed no trend over the last 10 years, but were almost never (1/33) improving. Within the rivers having declining returns, a broad range of patterns of decrease was observed. Within the rivers showing no trends a small fraction (4/13) improved notably in 1998. Within this rather pessimistic overall picture, stocks of the Northeast region (Scandinavia and Russia) seemed to be more of a concern than those from the Southwest region (UK, Ireland and France).

3.4.4 Survival indices

Estimates of marine survival for wild smolts from 10 stocks returning to homewaters (i.e. before homewater exploitation) and for 11 stocks returning to freshwater in 1998 are presented in Tables 3.4.4.1 and 3.4.4.2, respectively. Returns to homewaters are likely to present a clearer picture of marine survival than returns to freshwater because of variation in exploitation in coastal fishery. In Table 3.4.4.2, indices of survival are also provided for autumn age-0⁺ parr for the Nivelles River (France). This provides an approximation of marine survival as more than 80% of juveniles migrate after only one year in freshwater. In most areas marine survival was under the 5-year mean.

For 1SW fish route regression analysis showed no significant trend for the past 10-years but there was a significant downward trend for the past 5-years. No significant trend was noted for 2SW fish for the past 5- and 10-year periods.

Return rates of hatchery released fish may not always reflect the survival of wild fish due to differences in release conditions. Marine survival rates for six hatchery stocks are given in Table 3.4.4.3 and Table 3.4.4.4. For the past 10-year period, route regression analysis showed a downward trend for survival to home waters for 1SW and 2SW fish but no significant trend was observed for the past 5-year period.

In general, there appears to be an overall decreasing trend in survival.

3.4.5 Status of early-running (or spring) salmon

Early-running MSW salmon occur in the rivers of the central and southern European coasts. Catches of these fish have declined throughout the range, notably in Ireland, France and UK (England and Wales). Analysis of rod catch data for UK (Scotland) for each of the five separate months February - June show steeply declining trends (1952-present). The trends are progressively less pronounced through the sequence of months. New pairwise comparisons of each of the five monthly trends for February - June has shown that the developing trends diverged after about 1990. Since 1990, the February rod catch has declined rapidly. March and April catches have continued to decline at comparable rates, while May and June catches have recovered slightly - although they are still below the long-term average. In Scottish rivers, run-timing is strongly related to the distance fish move into rivers before they spawn. The graded trends for the monthly rod catch figures are reflected in graded egg deposition rates at different levels in the rivers. Egg deposition rates have declined most rapidly in the uppermost parts of catchments.

The Baddoch and Girnock Burns are upland spawning tributaries of the River Dee (UK: Scotland). They receive mostly early-running MSW fish and microtag data indicate that they fish enter the river before April. In 1998, the trap catch of adults ascending the Girnock Burn comprised only 29 fish of which only 11 were female. In the Baddoch Burn, 48 fish were captured of which only ten were female. In spite of greatly decreased levels of exploitation by estuary and coastal nets and the introduction in 1995 of an advisory (and effective) catch-and-release policy on the river, spawning escapement is at an extremely low level. In both streams, minimum egg deposition levels equivalent to about 40 females are considered to be required to ensure maximal smolt production. Current failure to approach these levels is a result of high marine mortality rates among early-running MSW fish.

3.4.6 Summary of status of stocks in the NEAC area

The analysis of smolt output data indicated that the temporal patterns were not consistent between different rivers or regions. Some rivers showed a significant improvement in smolt production whereas the smolt output of other rivers declined. A significant downward trend was detected for wild smolt survival (1 SW returns) over the past five years and for hatchery smolt survival (1 SW and 2 SW returns) over the past ten years.

In most cases, adult salmon counts in index rivers within the NEAC area increased from 1997 to 1998. However, over the last ten years, adult returns have been declining or showed no trend, and were improving in only one case. Analysis of attainment of conservation limits (CL) indicated variable status of salmon stocks in different rivers of the NEAC area. Some rivers have never or seldom reached their CL over the last 10 years, whereas others have been consistently above their CL. Many rivers that have reached their CL in most years show a decreasing trend in escapement, however, and no tendency to recover was observed for rivers with low escapement levels.

3.5 Evaluation of the Effects of the Suspension of Commercial Fishing Activity at Faroes

Since 1991 the Faroese fishermen have agreed to suspend commercial fishing for the salmon quota set by NASCO, in exchange for compensation payments. The number of fish spared as a result of this suspension is the catch that would have been taken if the fishery had operated, minus the catch in the research fishery. As for last year (ICES 1998/

ACFM:15), the Working Group concluded that the full quota would have been taken, had the quota purchase not been in effect. Thus, the maximum catch that would have been taken in 1997/98 would have been 380 t (Table 3.2.1.1).

Data on the discard rate in 1997/98 was obtained from the research fishery, while the age composition of the catch was derived from length-splits previously applied (ICES 1996/Assess:11). No new values were available for the proportion of farm escapees in catches, or to expected time to return to homewaters, so the same values used for the previous three years were applied. The assessment is shown in Table 3.5.1. This suggests that if the full quota was not taken, between 3,000 and 21,000 additional 1SW salmon and between 70,000 and 138,000 additional MSW salmon would have returned to homewaters each year from 1992 to 1998. For the 1997/98 season, the numbers of fish believed saved were 20,000 1SW and 103,000 MSW, respectively.

In addition, between 20,000-55,000 escaped farmed fish each season would have been saved from capture in the Faroese fishery, however data from tagging experiments suggest it is probable that almost all might be expected to return to Norway (ICES 1998/ACFM:15). The analysis carried out suggests that, for the 1997/98 season, up to 30,000 escaped farmed fish may have been saved.

Estimates (means of 1000 simulations) of the total numbers of 1SW and MSW salmon returning to homewaters (i.e., Pre Fishery Abundance estimates) in the NEAC area and to countries of northern and southern Europe are provided in Tables 3.6.2.1 and 3.6.2.2. The calculated additional returns represent between 6% and 14% of MSW fish and 0% to 1% of 1SW fish returning to homewaters between 1992 and 1998 (Table 3.5.1). However, data from adult tagging studies (Hansen and Jacobsen 1997), indicate that the majority (about 65%) of MSW salmon caught in the Faroes fishery would return to Scandinavian countries, Finland and Russia. If this were the case, they might have represented from 8% to 19% of MSW returns and from 0% to 1% of 1SW returns to northern European homewaters between 1992 and 1998 (Table 3.5.1). If stocks and fisheries had remained stable, total catches would have been expected to increase by approximately the same proportions in respective areas.

Catches in homewater fisheries in four areas of Europe (Table 3.5.2) were examined for any significant change following the suspension of fishing at Faroes in 1991. There have been significant reductions in catches for 1SW salmon in Northern Europe (Finland, Sweden and Norway) (R_{crit} , $p = 0.004$) and southern Europe (Ireland, UK (Scotland) and France) (R_{crit} , $p = 0.04$). No detectable change was noted for MSW catches in northern Europe (Finland, Sweden and Norway) or for adult counts to Russian rivers in the same period. (It should be noted that catches of MSW salmon in Europe in 1994 and 1995 should also have been affected by the suspension of salmon fishing in Greenland). MSW catches were significantly lower in the period following the cessation of commercial fishing at Faroes from 1992 to 1998, compared to the period 1987 to 1991 for southern Europe (UK [Scotland] and France) (R_{crit} , $p = 0.01$). Although the additional returns would have been expected to have contributed to catches and spawning stocks, it appears that any expected increase has been masked by other factors such as changes in marine survival or management measures in homewaters.

3.6 Expected Abundance of Salmon in the North East Atlantic for 1999/2000

3.6.1 Previous development of a NEAC - PFA model

In 1995, the Working Group presented a model to estimate the pre-fishery abundance (PFA) of salmon from countries in the NEAC area at the beginning of their second year in the sea (ICES 1995/Assess:14). The method employed a basic run-reconstruction approach similar to that described by Rago *et al* (1993b) and Potter and Dunkley (1993). The model estimated the PFA from the catch in numbers of 1SW and MSW salmon in each country. These were raised to take account of minimum and maximum estimates of non-reported catches and exploitation rates of the two age groups. Finally these values were raised to take account of the natural mortality between January 1 in the first sea winter, which is taken as the date they recruit to the first fishery (Faroes), and the mid-point of the respective national fishery season.

In 1997, the Working Group presented a Monte Carlo simulation ('@Risk' in Excel) to generate distributions around the estimated PFA values (ICES, 1997/Assess:10). The same minimum and maximum parameter values were used as previously (except where these were updated or corrected). These were thought to encompass the full range of true values and were therefore used as the limits of uniform distributions for each parameter in the simulation. The model was run separately to estimate the total numbers of maturing and non-maturing 1SW recruits in the NEAC area; and in southern and northern European countries each run was based on 500 simulations.

The Working Group further refined and updated this approach in 1998 (ICES 1998/ACFM:15). The Monte Carlo simulation was reformulated using the software package 'Crystal Ball' (Decisioneering, 1996) in Excel and was run separately for each country using 1000 simulations.

Thus, for each country in year ‘n’, the number of fish of sea age ‘i’ killed in fisheries (including unreported catches) (K_{ni}), the number returning to home waters (H_{ni}), the number of maturing 1SW recruits (P_{n1}), the number of non-maturing recruits (P_{nm}) and the number of spawners (W_{ni}) were estimated as follows:

$$K_{ni} = C_{ni} / (1 - R_{ni})$$

$$H_{ni} = K_{ni} / U_{ni}$$

$$P_{n1} = H_{n1} / e^{-M_{1t1}}$$

$$P_{nm} = H_{(n+1)m} / e^{-M_{mtm}}$$

$$W_{ni} = H_{ni} - K_{ni}$$

where suffix ‘i’ refers to age groups ‘i’, while ‘1’ and ‘m’ refer to the 1SW or MSW age groups specifically.

and: C = catch of salmon in numbers;

R = estimated proportion of the total catch that is unreported (*);

U = average level of exploitation of the salmon stock (*);

M = natural mortality on salmon greater than 1SW in the sea (*);

t = time between homewater fisheries and the time of recruitment (*).

Those variables marked with an asterisk (*) indicate variable for which minimum and maximum values were provided.

Full details of the model and a sensitivity analysis are provided by Potter *et al.* (1998).

3.6.2 Improvements to the NEAC - PFA model

The Working Group reviewed the model used to estimate pre-fishery abundance of salmon in the NEAC area, and the data inputs, and made the following improvements:

1. catch data and other parameter values were added for 1998;
2. parameter values for earlier years were modified where new data or new estimation procedures were available;
3. the numbers of recruits estimated from the catches in the distant water fisheries was allocated to national production on the basis of estimates provided by Potter (1996) for the West Greenland fishery and Hansen and Jacobsen (1997) for the Faroes fishery;
4. farm escapees were excluded from the recruitment estimates derived from catches in the Faroes fishery using estimates given by Hansen *et al* (In press);
5. estimated catches of salmon from UK (Scotland) in the UK (England & Wales) coastal drift net fishery were incorporated into the recruitment estimates for UK (Scotland).

The input data for the model for ten salmon producing countries in the NEAC area and for the Faroes and West Greenland fisheries (as updated for the 1998 assessment) are shown in Appendix 8a-8l. The maximum and minimum values denote the limits of the uniform distributions used in the Monte Carlo simulation.

Full results for each NEAC country are shown in Appendix 9a-9l. Tables 3.6.2.1 to 3.6.2.6 summarise the outputs from the simulation, giving the mean estimates of the numbers of returns (1SW and MSW), recruits (maturing and non-maturing 1SW), spawners (1SW and MSW) and total 1SW recruits (plus variances/ standard deviations). The tables suggest that the national stocks fall into two categories. Ireland, Norway, Russia and UK (Scotland) appear to be producing around 400k to 700k maturing 1SW recruits. With the exception of Ireland, these countries also produce 200k to 600k non-maturing 1SW recruits. Ireland and the remaining countries produce less than 100k maturing 1SW

recruits and less than 50k non-maturing 1SW recruits. The Working Group did not consider this to be inconsistent with their best understanding of the stocks.

3.6.3 Grouping of national stocks

The Working Group has previously divided the NEAC PFA estimates into two groups, representing the Nordic countries and Russia (northern Europe) and the UK, Ireland and France (southern Europe). However, the Working Group had previously noted particular similarities between the marine survival trends for the River Figgio (in southern Norway) and North Esk (eastern Scotland).

In 1998, the Working Group recommended that work be undertaken to assess whether alternative groupings might be more appropriate. Examination of time series of 1SW catches in south, mid and north Norway revealed that catches from the south and mid areas were correlated with each other but not with catches in the north. It may therefore be appropriate to split the Norwegian stock into two regions: (1) from the Swedish border to Lofoten, and (2) from Lofoten to the Russian border. The Working Group did not have the data to do this separation in the PFA model, but recommended that it be explored further in the coming year.

The Working Group has therefore used the following groups of countries to present the PFA data:

Southern European countries:	Northern European countries:
Ireland	Finland
France	Norway
UK(England & Wales)	Russia
UK(Northern Ireland)	Sweden
UK(Scotland)	Iceland

These groupings differ from those used in 1998 because recruitment estimates derived from catches at Faroes and West Greenland are now included in the national recruitment estimates and Iceland has been included in the Northern group.

Tables 3.6.2.1 to 3.6.2.6 show combined results from the PFA assessment for the Northern and Southern European groups and the whole NEAC area. The PFA of maturing and non-maturing 1SW salmon and the numbers of 1SW and MSW spawners for these areas are shown in Figures 3.6.3.1 to 3.6.3.3.

3.6.4 Trends in the PFA for NEAC stocks

The 95% confidence limits (dotted lines for PFA and vertical bars for the spawning escapement) shown in Figures 3.6.3.1 to 3.6.3.3 indicate the high level of uncertainty in this assessment. However, the Working Group recognised that the model provided an interpretation of our current understanding of national fisheries and stocks based upon simple parameters. Errors or inconsistencies in the output must largely reflect errors in our best estimates of these parameters.

Figure 3.6.3.1 suggests that there has been no overall trend in the recruitment of maturing 1SW salmon (potential grilse) in the northern countries, although the numbers have fluctuated quite widely around a level of approximately one million recruits. However, it must be noted that this pattern is largely driven by a simultaneous decline in Norway with an increase in Russia (Figure 3.6.4.1). The increase in the spawning escapement reflects the decrease in exploitation of these stocks in both the Faroes and homewater fisheries, particularly Norway and Russia.

Numbers of non-maturing 1SW recruits (potential MSW returns) for the northern group of countries appear to have fallen from approximately one million in the 1970s to about 0.6 million in the 1990s. The majority of this overall decline appears to have occurred in the mid 1980s, but recruitment also fell for a two year period in the late 1970s. This reflects very similar patterns in the estimated production of MSW salmon for Norway and Russia over this period. Reductions in the level of exploitation have resulted in a proportionally smaller overall decline in the spawning escapement, from an average of 330k in the early 1970s to an average of 250k in the past five years, although there have been quite large fluctuations (between about 200k to 400k) over the period.

For the southern European group of countries (Figure 3.6.3.2), the numbers of maturing 1SW recruits is driven largely by the Irish and UK (Scottish) stocks which are each estimated to have produced an annual average of about 650k fish

in the past 10 years. Recruitment for both of these countries has fallen substantially since the 1970s. Thus the southern group of countries show an overall halving of the number of maturing 1SW recruits over the period, with stocks falling to their lowest level in 1997.

The abundance of non-maturing 1SW recruits in the southern European countries is largely driven by the UK(Scottish) stocks which account for about 80% of the estimated numbers of recruits over the past 10 years. Ireland and UK(England & Wales) together account for about 15% of the recruits. All these countries have shown a very marked decline in the numbers of non-maturing 1SW recruits, such that overall production has fallen relatively steadily to about one third of its level in the early 1970s. For these stocks, reductions in exploitation does not appear to have kept pace with the stock declines and the spawning escapement has also fallen over the period.

3.6.5 Forecasting the PFA for NEAC stocks

In order to use the PFA estimates to provide catch advice, a forecast is required of the PFA of recruits in the year preceding the fisheries. Thus, for example, the PFA of non-maturing 1SW recruits must be predicted for 1999 if we are to provide advice for: the West Greenland fishery in 1999; the Faroes fishery (MSW stock) in 1999/2000; and homewater fisheries in 2000. Because the latest estimate of non-maturing 1SW recruits is for 1997, the PFA must be forecast two years ahead, as is currently practised for the North American assessment. For maturing 1SW stocks, a single year's projection is sufficient.

No new information was presented on methods to predict future levels of PFA from the historic time-series. In view of the uncertainty in these PFA assessments, the Working Group considered that the catch advice should be based upon qualitative extrapolations from the historic estimates. These are discussed in Section 3.8.

3.7 Development of Age-Specific Conservation Limits

3.7.1 Progress with river-specific conservation limits

The Working Group reviewed the progress that was being made with the development of river specific stock conservation limits, and alternative management approaches, in different countries in the NEAC area.

Finland and Iceland: No progress was reported.

France: Conservation limits have been set on a river-by-river basis for most of the north western stocks (33 out of 44 salmon rivers in France). The conservation limits are computed on the basis of the assessment of production potential (running water surface area) and the stock-recruitment relationship derived from the population dynamic survey of the River Oir (Prévost and Porcher, 1996; Porcher and Prévost, 1996). The TAC per river is adapted each year during the fishing season according to the annual fluctuations of returns. Provisional conservation limits have been developed for southern rivers (Loire and Adour).

Ireland: Potential spawning escapement requirements have been estimated for all rivers by applying reference egg deposition rates from the River Bush stock-recruitment relationship to the wetted area or catchment areas of each river to calculate spawning targets. While this provides a very approximate estimate, it is believed that the order of magnitude is broadly indicative of the spawning requirements for these rivers. This preliminary analysis is gradually being superseded by river specific analyses or on advice from regional fisheries managers.

Norway: Progress has been made with the use of GIS methods to estimate the productive capacity of Norwegian rivers using GIS (Erikstad *et al.* 1998). Digital maps (1:50 000) were used to estimate the wetted area of 11 Norwegian salmon rivers from the river mouths to the limit of upstream migration of salmon (usually easily defined by a waterfall) (Table 3.7.1.1). Tributaries and lakes were excluded in this preliminary analysis.

Production of salmon smolts in the River Imsa, where emigrating smolts have been counted since 1976, has shown an average annual production of about 15 individuals per 100 m² (Jonsson *et al.* 1998). Smolt production in the River Kvassheimsåna which is in the same area as River Imsa were estimated at 15 individuals per 100 m² in a single year. Johnsen *et al.* (1999) reported a time series of smolt production estimates from a large area of the River Orkla since 1983, based on tagging and recapture, to be an average of seven smolts per 100 m² with annual variations from four to eleven. Data from these investigations were modified and transported to other systems after personal communications and discussions with biologists working on the different rivers, taking into account local conditions such as temperatures and water flows, and unpublished data on electrofishing surveys and habitat quality. Guess-estimates of smolt production per unit of area were then applied for the individual rivers, and the estimated smolt productions are

shown in Table 3.7.1.1. There was a significant relationship between estimated smolt production and mean catch in the last 20 years ($r^2=0.63$, $p=0.02$, $n=8$), suggesting that the provisional smolt production estimates are within reasonable limits.

The use of GIS will be further developed to produce objective smolt production estimates based on habitat area, and should incorporate information on river gradient, local vegetation and estimates of parr densities.

Russia: Provisional conservation limits have been set for the Kola rivers where the fisheries have been conducted for 30-40 years at estuary barrier fences which have provided comprehensive catch statistics and biological data. Conservation limits have been defined for five rivers as MSY points on stock recruitment curves as recommended by the Working Group. For those rivers where habitat data are available, conservation limits have been established by transporting reference points (2.73 eggs per m^2 for the Barent Sea and 3.85 eggs per m^2 for the White Sea rivers). An approach using total catchment area has been applied for other rivers.

Sweden: The evaluation and further development of the status of salmon stocks on the Swedish west coast is being considered by a Working Group established in 1998. Provisional estimates of salmon smolt production are now available for 17 rivers in western Sweden (Table 3.7.1.2).

UK (Northern Ireland): Spawning targets that have been set to date range from single river targets derived from river-specific stock-recruitment data (Rivers Bush and Foyle) to targets derived from the transport of these data to other systems. On the River Foyle spawning targets are being used for the management of fisheries, while the majority elsewhere are still being developed and are mainly used for illustrative and modelling purposes at present.

UK (England & Wales): Provisional conservation limits (referred to as 'spawning targets') have been developed for all principal salmon rivers. These are being reviewed and finalised as Salmon Action Plans are developed for each river; a Ministerial Direction issued to the Environment Agency in September 1998 requires that the Salmon Action Plans be completed for 68 salmon rivers by the year 2002. The 'spawning targets' are set using a nationally agreed methodology (Environment Agency 1998). This adjusts a stock-recruitment relationship for the River Bush, UK (Northern Ireland) according to the quality and quantity of juvenile habitat in each river, derived from a simple habitat model (Wyatt and Barnard 1997).

UK (Scotland): Previous studies of genetic structuring among salmon populations in Scottish rivers has identified important structural differences within catchments. Radio-tracking studies in several rivers have demonstrated that those fish homing to spawn in locations distant from the sea enter fresh water earlier than fish homing to spawn in locations lower in the same catchments. Habitats left vacant by particular seasonal runs is not taken up by fish of other types. These observations suggest that the appropriate biological scales for setting conservation levels or targets for Scottish rivers lies far below the levels considered appropriate elsewhere. In order to overcome these difficulties an approach is being developed that is appropriate for Scottish circumstances. It is intended to derive estimates of optimal values for escapement based upon an analysis of rod catch data and estimates of local juvenile production.

3.7.2 National conservation limits - Lagged spawner analysis

In 1998, the Working Group noted that it was likely to be a number of years before conservation limits were developed for all river stocks in the NEAC area. A method was therefore proposed for estimating national conservation limits based upon the output of the PFA analysis described in Section 3.6. A full description of the model along with a sensitivity analysis was provided by Potter *et al.* (1998).

In brief, the model provides a means for relating the estimates of spawners and recruits derived from the PFA model. This is addressed by converting the numbers of 1SW and MSW spawners into numbers of eggs deposited. Thus, in each country and for each year the total egg deposition (E) may be estimated as:

$$E = (W_1 \times F_1 \times G_1) + (W_m \times F_m \times G_m)$$

where: suffixes '1' and 'm' refer to 1SW and MSW age groups respectively

and: W = the number of spawners in the age group (from the PFA simulation model);

F = the % female in the age group;

G = the average number of eggs produced by a female in the age group.

The approach assumes that there have been no significant changes in the egg production or in the proportion of females for 1SW and MSW salmon over the time period. Males are also ignored in the foregoing analysis, the assumption being that their numbers have not limited the deposition of fertilised eggs, and thus the production, during the period 1971 to the present.

The egg deposition in year 'n' is assumed to contribute to the recruitment in years 'n+3' to 'n+8' in proportion to the numbers of smolts produced of ages 1 to 6 years. Thus the number of 'lagged eggs' (L) which will contribute to the recruitment of maturing and non-maturing 1SW fish in year 'n+8' is estimated as:

$$L_{n+8} = (E_n \times p_6) + (E_{n+1} \times p_5) + (E_{n+2} \times p_4) + (E_{n+3} \times p_3) + (E_{n+4} \times p_2) + (E_{n+5} \times p_1)$$

where: E_n = the estimated number of eggs deposited in year 'n'

and p_i = the proportion of smolts of age 'i'.

The lagged egg deposition estimates for each national stock is given in Appendix 10a-10j along with the estimated numbers of 1SW recruits, which have been carried over from the PFA analyses. The relationships between the lagged eggs ('stock') and 1SW recruits are also shown in the Figures included in Appendix 10a-10j.

The plots of lagged eggs (stock) against the 1SW adults in the sea (recruits) have been presented as 'pseudo-stock-recruitment' relationships. As in 1998, three non-parametric methods have been used to estimate conservation limit 'options' from these relationships. These have been proposed as methods for estimating the minimum biological acceptable level (MBAL) for marine fish stocks (ICES 1993/Assess:12). (Conservation limits for salmon have been defined as being equivalent to MBAL (ICES 1995/Assess:14)). These methods therefore provide approaches for estimating provisional conservation limits from the 'pseudo-stock-recruitment' relationships.

These are:

- Option 1: the minimum observed spawning stock level [i.e., $CL_{opt1} = \min L$],
- Option 2: the stock size where the 90th percentile of survival intersects the median recruitment level. [i.e., $CL_{opt3} = (R/L)_{90\%ile} \times R_{med}$], and
- Option 3: the stock size where the 90th percentile of survival intersects the 90th percentile of recruitment (Serebryakov, 1991); [i.e., $CL_{opt2} = (R/L)_{90\%ile} \times R_{90\%ile}$].

To be compared with any forecast of PFA, the egg deposition conservation limit levels must be converted back to fish numbers. NASCO has also asked that the conservation limits be split by age-groups; this is clearly a necessity where decisions have to be made about the management of fisheries exploiting predominantly one age group of fish. As in 1998, the egg deposition conservation limit has been converted to numbers of 1SW and MSW salmon based upon the average age composition of the spawning stock in the past 10 years. These results are shown in Appendix 10a –10j. The three conservation limit 'options' derived for each country are summarised in Table 3.7.2.1. Where river specific conservation limits have been derived, these are provided as a fourth option.

3.7.3 Evaluation of conservation limit options

As with the output from the PFA model, the lagged egg deposition analysis provides a further interpretation of our best understanding of the dynamics of national stocks. While the concept of 'national stocks' has little meaning biologically, it is possible, mathematically, to consider a national stock-recruitment relationship as the sum of a large number of population stock-recruitment relationships. The Working Group noted the following points about the conservation limit options derived for each country from this model.

In UK (England & Wales) and France conservation limits have been independently derived for every river, although some values are still provisional. The sum of these river specific conservation limits in UK (England and Wales) is 226 million eggs. This lies between the conservation limits given by Option 2 (205 million eggs) and Option 3 (253 million eggs) in the lagged egg deposition assessment. Similarly for France, the sum of the river specific conservation limits (55 million eggs) lies between Option 2 (47 million eggs) and Option 3 (70 million eggs) conservation limits from the lagged egg deposition analysis.

Although conservation limits have not been derived for all rivers in Ireland and UK (Northern Ireland), the output from the lagged egg deposition analysis was consistent with preliminary analyses by alternative methods such as those proposed by the Workshop on Setting Conservation Limits for salmon in the NE Atlantic (ICES 1998/ACFM:13).

The Working Group had some concerns about the estimated conservation limits options for UK (Scotland), which appeared rather high in comparison with other countries. The high conservation limit estimates may imply substantial differences in the dynamics of Scottish stock, in comparison to Norway in particular, or over or under-estimates of some of the input parameters. There are substantial differences between Scottish and Norwegian stocks, for example in the time period over which the fish return to freshwater, but the effects of these differences on population dynamics is not known. Errors in the input data are most likely to be in the estimated exploitation rates; changes in other parameters are either unlikely to have significant effects on the conservation limit options in this case (e.g. unreported catch) or would be expected to have similar effects on all the national stock assessments (e.g. major changes in 'M').

The Working Group felt that they had no basis for modifying the data inputs for the model without further information and concluded that the conservation limit estimates remained the best available information on which to base the catch advice. However, it was recognised that the uncertainty in these data must be taken into account when providing catch advice.

In 1998, the Working Group provided three conservation limit options for each country; ACFM chose to use the minimum summed value (Option 1), which is clearly the least precautionary, in the advice to NASCO. Following further review of the approach, the Working Group decided to select the most appropriate conservation limit option for each country based upon the nature of the 'pseudo-stock-recruitment relationships' (Appendices 10a-10j) and local knowledge. This evaluation is summarised below:

Country	Option	Reason
Finland	3	Recruitment lower at Option 1 and 2 levels.
France	4	Based upon river specific estimates.
Iceland	1	Options 1 & 2 equal; no increase in recruitment for Option 3.
Ireland	3	Very wide spread of historic stock estimates.
Norway	3	Recruitment lower at Option 1 and 2 levels.
Russia	1	No decrease in recruitment at Option 1 level.
Sweden	3	Recruitment lower at Option 1 and 2 levels.
UK(Eng. & Wales)	4	Based upon river specific estimates.
UK(N. Ireland)	3	Recruitment lower at Option 1 and 2 levels.
UK(Scotland)	2	Recruitment lower at Option 1 level.

The selected options have been summed in the appropriate stock groups. These are then increased to take account of the natural mortality between recruitment and the time of return in order to provide spawner escapement reserves (SERs) for maturing and non-maturing 1SW salmon from the Northern and Southern stock groups. The SERs are shown as horizontal lines in Figures 3.6.3.1 and 3.6.3.2; the dashed line indicates that these SERs may be less appropriate for evaluating the historic status of stocks. The SERs are not shown on the total NEAC data (Figure 3.6.3.3) because evaluation of stocks against conservation limits is thought to be inappropriate at that level.

3.8 Catch Options or Alternative Management Advice

3.8.1 Overview of the provision of catch options or management advice

The Working Group has been asked to provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits in the NEAC area. The Working Group reiterated their concerns about applying TACs to mixed stock fisheries, particularly when many individual river stocks and sub-river populations are known to be at unsatisfactorily low levels. Annual adjustments in TACs based on changes in the mean status of the stocks is unlikely to provide adequate protection to the individual river stocks that are most heavily exploited by the fishery or are in the weakest condition.

The Working Group also emphasized that ‘national’ stock conservation limits are not appropriate for the management of homewater fisheries, particularly where these exploit separate river stocks. This is both because of the relative imprecision of the national conservation limits and because they will not take account of differences in the status of different river stocks or sub-river populations. Nevertheless, the Working Group accepted that the combined conservation limits for the main stock groups (national stocks) exploited by the distant water fisheries could be used to provide catch advice for these fisheries.

3.8.2 Catch options and management advice for 1999/2000

In 1998, the Working Group provided catch advice for Northern and Southern European stock complexes. The Working Group reiterated the view that ‘national’ stock conservation limits are not appropriate for the management of homewater fisheries, particularly where these exploit separate river stocks. This is both because of the relative imprecision of the national conservation limits and because they will not take account of differences in the status of different river stocks or sub-river populations.

In view of the uncertainties expressed above about the most appropriate stock groupings and the preliminary nature of the conservation limit estimates, the Working group considered that it would be inappropriate to provide quantitative catch options at this stage. However, the Working Group felt that the following qualitative catch advice was appropriate based upon the PFA data and estimated SERs shown in Figures 3.6.3.1 and 3.6.3.2:

Maturing 1SW stocks: very few 1SW salmon have been caught outside homewater fisheries in Europe, even when fisheries were operating in the Norwegian Sea. The Working Group therefore recommends that management of maturing 1SW salmon should be based upon local assessments of the status of river or sub-river stocks.

Northern European MSW stocks: These are the main stocks that have contributed to the fisheries in the Norwegian Sea in past years. The PFA of non-maturing 1SW salmon from Northern Europe has been declining since the mid 1980s and is now approaching the conservation limit estimates. The exploitable surplus has declined from over 800,000 recruits in the 1970s to around 250,000 recruits in 1996 and 1997. The Working Group therefore suggests that great caution should be exercised in the management of these stocks particularly in mixed stock fisheries. Management of single stock fisheries should be based upon local assessments of the status of stocks.

Southern European MSW stocks: This group includes the main European stock contributing to the West Greenland fishery. The PFA of non-maturing 1SW salmon from Southern Europe has been declining since the 1970s and the Working Group’s analysis suggests that it fell below the conservation limits in 1996 and 1997. Simple projection of these data by eye suggests that the PFA is also likely to fall below the conservation limits in 1999. The Working Group considers that extreme caution should be exercised in the management of these stocks in mixed stock fisheries and that reductions in levels of exploitation should be pursued. Management of single stock fisheries should be based upon local assessments of the status of stocks.

3.9 Catches of Post-smolts in the Norwegian Sea and Adjacent Areas

3.9.1 Post-smolt surveys 1990–1998

Post-smolt sampling cruises have been undertaken by the Institute of Marine Research (IMR), Norway since 1990 with the primary aim of describing the post-smolt distribution in the northeast Atlantic (Figure 3.9.1.1). Similar cruises were undertaken by Fisheries Research Services (FRS) Scotland in 1996 and 1997. The results of these surveys were reported to the Working Group in 1998 (ICES 1998/ACFM:15). In summary, a surface trawl technique was developed and proved successful in capturing post-smolts. Around 1,000 hauls were undertaken covering an area from the south west of Ireland (50°N) to the east of Bear Island (75°N), and in the order of 1,000 post smolts and 25 1SW salmon were caught. While large concentrations of post-smolts were found within the strong north-east running slope current along the north-west European continental shelf edge, large numbers were also caught in the Norwegian Sea.

In 1998, IMR undertook six further cruises (Table 3.9.1.1), extending the areas surveyed to include both the Greenland Sea and the Barents Sea. Post-smolts were successfully captured in both the Norwegian and Greenland Seas and the Norwegian fjords (Figure 3.9.1.2). In contrast, no post-smolts were caught in the Barents Sea. Analysis of the distribution patterns of post-smolts caught in Norwegian and Scottish cruises since 1990 shows that capture sites coincide, to a large extent, with the prevailing surface current patterns in the area. This suggests that the strong Atlantic Slope current and the Norwegian coastal current (Figure 3.9.1.3) are the main carriers of post-smolts to the northern feeding areas. Analyses of the hydrographical regimes at the capture sites show a strong concentration of the captures to the 9.0-10.9°C temperature interval and in salinities of ≥ 35.000 ppm (Figure 3.9.1.4), indicating a preference for the

warm, saline, productive Atlantic water masses over the colder and less saline Arctic water in the north west and the warmer but less saline waters of the Norwegian coastal current in the east.

Examination of the smolt age distribution of the fish captured in the different areas in 1998 supported the conclusion from earlier cruises that due to their young sea age a relatively high proportion of the post-smolts caught in the Norwegian Sea was of southern European origin. This is in contrast to fish caught west of Lofoten that were older, and those caught in fjords in west Norway where the smolts were mainly 3 and 4 years of age (Figure 3.9.1.5).

FRS conducted an inshore survey (within the limits of the Moray Firth) on the north-east coast of Scotland (Table 3.9.1.1). A large number of post-smolts were caught and analysis of stomach contents did not indicate any shortage of food. In contrast to the Norwegian findings from offshore sampling surveys, no relationship was evident between the inshore distribution of post-smolts and temperature and salinity gradients.

The Polar Research Institute of Marine Fisheries and Oceanography (PINRO) carried out a survey in the northern Norwegian Sea (Table 3.9.1.1). No post-smolts were captured in this area. Interestingly, four adult salmon, three of which were classified as farmed salmon were caught.

3.9.2 Estimates of post-smolt by-catch in pelagic fisheries

Post-smolt and herring seem to overlap spatially mostly in July early August in the areas north of 68°N (Holst *et al.* 1998). The purse seine fishery for herring takes place in the areas west of Iceland up to the Jan Mayen Island as early as April and into June and is therefore not likely to intercept young salmon. In 1998, a limited effort was made by the Fishery Laboratory of the Faroes to collect information on salmon by-catches in a Faroese purse seine fishery for herring which was taking place in June in these areas. Crew members on two of ten Faroese purse seine vessels were asked to look specifically for post-smolts when sampling the herring catch for mandatory documentation of weight distributions to the buyers on land. No post-smolts were reported. In addition post-smolts were not found in a sample of 1-3% of the landed catch of herring from one vessel and mackerel from another specifically screened for the presence of post-smolts.

The Fishery Laboratory of the Faroes and the Russian Polar Institute (PINRO) have initiated a bilateral collaboration on the by-catch of salmon post-smolts north of the Faroese in the 1999 fishery for herring and mackerel.

Information by Belikov *et al.* (1998) shows that both the migratory pattern and the distribution of older year classes of mackerel are very similar to that of the post-smolts. The mackerel start a northward summer migration from the waters north and west of Ireland in May, and some stock components may migrate as far into the Norwegian Sea to 74°N in July before they turn back to their southerly winter feeding areas. The stocks are believed to be large at the moment and the seasonal distribution changes somewhat with variations in hydrographical conditions. Catch distribution diagrams for 1989-97 for mackerel indicate for some years a strong overlap with the inferred northward migratory routes of post-smolts in June and July in the Shetland Faroes Channel, the North Sea and the Norwegian Sea (Belikov *et al.* 1998). One Norwegian Carlin tagged post-smolt found in a mackerel trawlcatch in 1996 is the only evidence of interception so far. The fishery with the greatest potential for catching post-smolts is probably the trawl fishery for mackerel in the Faroes EEZ and the international area of the Norwegian Sea. This fishery is presently at a high level and is not anticipated to diminish in the near future.

Observing post-smolts in large herring and/or mackerel catches is difficult due to their resemblance both in size and coloration. To be certain of the absence of post-smolts in such catches the whole catch must be screened. Assessment of by-catches on board commercial fishing vessels may prove too time consuming to be carried out in practice. However, efforts should be made to arrange screening of whole catches at landing sites.

Although preliminary investigations have been carried out, the Working Group was unable to provide estimates of the by-catch of post-smolts in pelagic fisheries. While observations on catch on pelagic fishing vessels is a possibility, in reality this is likely to provide only a qualitative assessment of post-smolt by-catch. An alternative approach would be to carry out directed research fisheries with similar gear, locations and time as commercial fishing boats or carry out co-operative fishing with a commercial fishing vessel.

Despite the limitations of the current data, the Norwegian salmon surveys seem to indicate a clear correspondence with the trawl depth related to the on-surface position of the upper trawl panel, and the likelihood of catching post-smolts where they are more densely distributed. A simple precautionary measure against post-smolt catches in commercial fisheries may therefore be to negotiate that the fleet does not operate their trawl with a flotation that will keep the floatline closer to the surface than 5 -10 m during longer periods of towing.

The ICES Working Group on Northern Pelagic and Blue Whiting Fisheries, Working Group on the Assessment of Mackerel, Horse Mackerel Sardine and Anchovy, and the Herring Assessment Working Groups asked WGNAS to expand on its' request for information useful in the assessment of potential problems with by-catch of Atlantic salmon in pelagic fisheries. Details required are as follows:

- May: The number of vessels fishing purse seines and the number of trawls at the surface in which the upper panel is close to the surface and keeps within 0-15 m during prolonged periods of a tow. It would also be useful to know if the surface trawl is fitted with extra flotation on the upper panel and sweepers. Areas of interest in May are ICES Statistical areas IV b-c and VII a-K (see attached map). Catches, swept area (or information allowing the calculation thereof), CPUE for such gear in May and possible recordings of post-smolt (12 -17 cm salmon) and older salmon (≥ 30) in these catches. Other types of gear and trawl tows carried out with the upper panel deeper than 15 -20 m are of lesser importance;
- June: Same catch characteristics as above for the above types of gear and depths but recorded in ICES areas VI a-b; IVa and Vb1-2. Possible by-catch of post-smolt and salmon in this month will comprise size groups 13–20 cm and ≥ 30 cm, respectively;
- July: Same catch characteristics as above for the above types of gear and depths but recorded in ICES area IIa delineated by -5°W to 13°E longitude and 66° to 72°N latitude. Possible by-catch of post-smolt and salmon in this month will comprise size groups 16–26 cm and ≥ 30 cm, respectively;
- August: Effort and catches by the above specified gear in ICES area IIb delineated by -3°W -21°E longitude and 72° -76°N latitude. Possible by-catch of salmon may comprise all sizes ≥ 28 cm.

It is recommended that the sampling programme for post-smolt should be maintained and further extended with surveys in July in the Norwegian Coastal current along the northern most coast of Norway and Russia and into the Barents Sea.

3.10 Data Deficiencies and Research Needs in the NEAC Area

3.10.1 Progress on items cited in 1998 report of NASWG

1. Estimates of marine mortality of salmon should be re-examined in the North-East Atlantic, and causes for this mortality should be identified and quantified.

No substantial progress was reported.

2. The Working Group strongly endorses the continuation of the post-smolt surveys in the North-East Atlantic, and recommends this to be extended to presently uncovered areas.

A single in-shore cruise was undertaken by UK (Scotland), between 14-25 May, in the inner Moray Firth on the north-eastern coast of Scotland.

Six cruises covering three fjords in south-west Norway captured both wild and escaped-farmed smolts. Norway extended post-smolt surveys, for the first time, beyond the 73.5°N in the northern Norwegian Sea and into the Barents Sea, as far as 40°E longitude. Three cruises were undertaken.

3. Efforts should be made to provide estimates of by-catch of salmon in marine waters.

Progress is reported in Section 3.9.

4. The Working Group recommends that the Working Group on Northern Pelagic and Blue Whiting Fisheries, the Working Group on the Assessment of Mackerel, Horse Mackerel, Sardine and Anchovy, and the Herring Assessment Working Group are asked for data regarding by-catches.

A request for data has gone to the Working Groups via ICES.

5 The Working Group recommends a continuation of the research fishery at Faroes.

A small research fishery took place in late winter, 1999.

6. Alternative ways to group salmon stocks, or stock complexes should be examined to improve the catch advice for salmon in the North-East Atlantic.

Studies of catches of ISW fish in Norway showed a correlation between the southern and mid-Norway portions of the catch. No correlation was found between these catches and those made in northern Norway (see Section 3.4).

7. The quality of data used to set conservation limits in the North-East Atlantic should be improved and provided for smaller stock complexes. Furthermore, a sensitivity analysis of the input parameters to the pre-fishery abundance model should be carried out.

A joint paper addressing the item was presented at the annual statutory meeting of ICES in September, 1998. Additional progress is reported in Sections 3.6 -3.8.

8. More information is required on a river by river basis relating to catches, exploitation rates and habitat assessment and this should be referenced to the appropriate scale (eg., tributary populations etc.). Specific information on required age class composition of the stocks should be established on a river by river basis (historical and current).

See Item 12.

9. Life history models are required for as many index rivers as possible.

No action was reported but models are under development.

10. Transportability of existing targets derived from known S/R relationships must be evaluated in comparison with other indices of abundance

No progress was reported.

11. Further refinement is required to the model to estimate PFA and Conservation Limits particularly with regard to the examination of the input data from each country to explain differences between the model output and current estimates of abundance from other analyses.

See Sections 3.6 -3.8.

12. Further research and development is required, particularly with regard to establishing stock size (counters) and relating productivity to suitable habitat area (catchment surveys, juvenile production studies and application of GIS and other techniques).

A comprehensive programme of fish counter installation is being carried out in Ireland. There are approximately 135 main stem salmon producing rivers in Ireland. It is hoped to have a total of 30 fish counters operational. Several Geographic Information Systems (GIS) are being developed for important catchments which are aimed at producing productivity estimates from habitat indices.

In Norway, some counters have been installed and testing is in progress and the development of a GIS application to estimate smolt producing areas in rivers is under-way.

In UK, a collaborative investigation is underway on four rivers to investigate the use of hydroacoustic counters and to develop validation procedures.

The two existing counters in the River Foyle Fisheries Commission area, which is jointly managed by Ireland and the UK (N. Ireland) are being supplemented by another three. It is planned to install up to five more in rivers elsewhere. Habitat area is being quantified using GIS with a view to refining conservation limits and defining relationships between productivity and habitat.

In UK (Scotland) progress has been made in developing new statistical methods to derive measures of adult abundance from rod catch data.

On the River Teno a split-beam hydroacoustic counter system (SIMRAD) underwent preliminary testing. Pilot studies will continue. Possible development of a permanent monitoring system will be decided after the 1999 experiment.

13. The implications of combining required adult escapement levels over districts must be examined and the scale to which this is appropriate identified.

No action reported.

3.10.2 Continuing requirements for data, research and monitoring

1. More research into the biology of salmon in the early marine phase is required and extension of recent research on the biology of post-smolts is recommended. Competitive interactions with other marine species should be explored. Additionally, by-catches of post-smolts in marine fisheries for other species should be monitored and estimates of mortality from this source should be derived. There is a continuing requirement to monitor trends in marine mortality for a wider range of stocks than at present, and to identify causes for current low levels of marine survival. In the latter context, it is noteworthy that an ICES Workshop on the Usefulness of Scale Growth Analyses and Other Measures of Condition in Salmon will be held in Amherst, USA in July, 1999.

2. It is recommended that a research fishery at Faroes should be continued and that material gained during previous study should continue to be worked-up.

3. The quality of data used to set conservation limits should continue to be improved and the PFA model should continue development. More and better input data should be obtained from a greater range of sources. Data collection should be targeted at finer scales. New ways of handling data, including GIS applications, and particularly new methods for grouping sub-divisions (eg., populations, or alternative divisions based on biological characteristics such as sea-age or run-timing) should continue to be explored, developed and validated. In particular, sensitivity analyses are essential to assess the confidence with which data derived from the theoretical models can be used in an applied management context.

4. Assessment methods for juvenile salmon and for freshwater habitat parameters should continue to be developed. Attempts should be made to couple these parameters with adult return parameters, via life-history models of appropriate scale. Habitat and life-history variables should be used together to examine the extent to which stock-recruitment relationships from a limited range of index rivers are transferable to other rivers.

5. The status of southern and central European rivers with respect to *Gyrodactylus* species, and particularly *G. salaris*, should be established without delay. Monitoring of the spread and occurrence of *G. salaris* should be encouraged in salmon-producing countries, and in other countries that are possible sources for transfer of the parasite.

Table 3.2.1.1 Nominal landings of Atlantic salmon by Faroese vessels in years 1982-1998 and the 1981/1982 to 1998/1999 fishing seasons.

¹ Common licence for salmon and seatrout.

² Introduction of quotas/fisherman, obligation to declare the catches.

³ The number of licences indicates only the number of fishermen (or boats allowed to fish for salmon. It overestimates the actual number of fishermen fishing for salmon up to 2 or 3 times.

⁴ Adour estuary only southwest of France.

⁵ Since 1995 data for Ireland are provisional.

1 “+” indicates a small but unquantified catch.

2 Smolts released for enhancement of stocks or rod fisheries are categorised as wild

3 Fish released for mitigation purposes and not expected to contribute to natural spawning.

4 Data from 1994 onwards is figure reported in national catch statistics, previous years’ data have been calculated from a sampling programme.

5 Breakdown of catch not yet available.

Table 3.3.7.2 Proportion of farmed Atlantic salmon (unweighted means) in marine fisheries in Norway 1989-1998. n=number of salmon examined.

¹Estimate based on counter and catch figures.

²Estimates based on counter catch figures.

³Estimate based on external tag recoveries and before 1994 on assumed 50% exploitation in the river brood stock fishery and in 1994-96 on mark-recovery estimates.

⁴HR in R. Drammen, R. Imsa and R. Lagan are pooled groups of 1+ and 2+ smolts.

⁵Provisional figures.

⁶Net only.

W = Wild

HR = Hatchery reared.

'-' = no data

¹ Major tributary of River Teno² Tributary of River Teno. Smolt traps out of commission since 1995.³ Juvenile survey represents mean fry and parr abundance (number 100 m² caught by electrofishing) at 35, 10 and 12 sites respectively.⁴ Smolt trap catch represents part of the run.⁵ Incomplete data. Minimum numbers due to high water levels.

⁶ Estimate of 0+ parr population size in autumn.

⁷ Juvenile surveys represent index of fry (0+) abundance (number per 5 minutes electrofishing) at 137 sites, based on natural spawning in the previous year.

⁸ These smolt counts show effects of enhancement. ⁹ Influenced by enhancement (fry releases). ¹⁰ Minimum estimate due to severe flooding. ¹¹ Smolt counts too small for estimate.

Table 3.4.2.2 Status of stocks in the North East Atlantic. Summary of trend analyses on smolt counts and survival based on a non-parametric method (1000 iterations). (p <0.1 means significance upward, trend, p>0.9 means significant downward trend).

¹Minimum count.

In the UK(Scotl.)Girnock, the trap is located in the Girnock Burn, a tributary in the upper reaches of the River Dee (Aberdeenshire). In the UK(Scotl.) N. Esk, counts are recorded upstream of the in-river commercial fishery and most important angling fishery. Thus, the counts do not necessarily reflect the numbers of fish entering the river.

a. NASCO quota agreed for the calender year in the latter part of the fishing season.

b. Expected no. landed in year y calculated from quota: $\text{Sum}(p_i/w_i) \cdot \text{Quota}_y$, p_i is proportion of age group i , $i = 1; 2$ and $2+SW$, and w_i is mean weight of sea age i .

c. No data, estimated from mean discard rate 1992-95.

d. No data, mean values from 1992-95 data.

e. Includes farmed escapees.

f. Data not yet available, mean value from 1994-1996 data

Table 3.5.2

Results of non-parametric ratio analysis to examine changes in homewater catches or returns after the cessation of commercial fishing at Faroes in 1991

Type of data	Area considered	Periods compared	p value	Effect	p
1SW catches in Northern Europe	Finland, Sweden, Norway, Iceland	1987-91 vs 1992-96	0.004	Lower catch	
	Norway only	1987-91 vs 1992-96	< 0.001	Lower catch	
1SW catches in Southern Europe	Ireland (total catch), UK(Scot), UK (E&W), France	1987-91 vs 1992-96	< 0.04	Lower catch	
MSW catches in Northern Europe	Finland, Sweden, Norway, Iceland	1987-91 vs 1992-96	0.12	Not significant	
	Norway only	1987-91 vs 1992-96	0.12	Not significant	
MSW catches in Southern Europe	UK (Scot), UK (E&W), France	1987-91 vs 1992-96	0.01	Lower catch	
Russian adult counts All ages	R. Varzuga, Ponoy, Kola, Yokanga, Zap Litca, Tuloma, Kitsa, Ura	1988-91 vs 1991-98	0.838	Not significant

4 FISHERIES AND STOCKS IN THE NORTH AMERICAN COMMISSION AREA

4.1 Description of Fisheries

4.1.1 Gear and effort

Canada

The 23 areas for which the Department and Fisheries and Oceans (DFO) manages the salmon fisheries are called Salmon Fishing Areas (SFAs); for Québec, the management is delegated to the Ministère de l'Environnement et de la Faune and the fishing areas are designated by Q1 through Q11 (Figure 4.1.1.1). Harvest (fish which are killed and retained) and catches (including harvests and fish caught-and-released in recreational fisheries) are categorised in two size groups: small and large. Small salmon in the recreational fisheries refer to salmon less than 63 cm fork length, whereas in commercial fisheries, it refers to salmon less than approximately 2.7 kg whole weight. Large salmon in recreational fisheries are greater than or equal to 63 cm fork length and in commercial fisheries refer to salmon greater than or equal to about 2.7 kg whole weight.

Three user groups exploited salmon in Canada in 1998: Native peoples, commercial fishers, and recreational fishers. The following management measures were in effect in 1998:

Native peoples' fisheries: In Québec, Native peoples' food fisheries took place subject to agreements or through permits issued to the bands. There are nine bands with food fisheries in addition to the fishing activities of the Inuit in Ungava. The permits generally stipulate gear, fishing effort and catch limits. In the Maritimes and Newfoundland (SFAs 1 to 23), food fishery harvest agreements were signed with several Native peoples' groups (mostly First Nations) in 1998. The signed agreements often included allocations of small and large salmon. For the first time, harvests by Native peoples in Labrador (SFA 1) are also reported. Harvests which occurred both within and outside agreements were obtained directly from the Native peoples or, estimated by local enforcement staff, in the case of Labrador. Harvest by Native peoples with recreational or commercial licenses are reported under the recreational and commercial harvest categories.

Commercial fisheries: The moratorium which was placed on the commercial fishery in insular Newfoundland in 1992 continued in 1998. In addition, the commercial fishery in southern Labrador (SFA 14B) remained closed in 1998, as in 1997. The commercial fishery in the remainder of Labrador was closed in 1998, with a voluntary buyback of licenses offered (Table 4.1.1.1). Commercial fisheries in Québec in 1998 occurred only in zone Q9 (July 1 to August 23) as the commercial quota normally fished by Native peoples' in Ungava Bay (zone Q11) was closed. The quota for Q9 in 1998, established in terms of number of fish, was the same as in 1997, however, a voluntary buyback of licenses was announced for this fishery before the season and resulted in many fishermen not fishing.

Recreational fisheries: Recreational fisheries management in 1998 varied by area (Figure 4.1.1.2). Except in Québec and Labrador (SFA 1 and 2), only small salmon could be killed and retained in the recreational fisheries. The seasonal bag limits in the recreational fishery remained at eight small salmon in New Brunswick (SFA 15, 16) and in SFA 18 of Nova Scotia, although in SFAs 15 and 16, the small salmon retention limit was reduced from two to one fish and the maximum daily catch limit was reduced from four to two fish. For the Miramichi River only, the daily catch limit was increased to four fish per day after a mid-July in-season review. In SFA 17 (PEI), the season and daily bag limits were 7 and 1 respectively. Catch-and-release fishing only for all sizes of Atlantic salmon was in effect in SFA 19 of Nova Scotia and on ten rivers in Newfoundland. SFAs 20-23 of Nova Scotia and New Brunswick was closed to all salmon angling, except for four acid-impacted rivers on the Atlantic coast of Nova Scotia, where retention of returning small hatchery salmon was allowed. For insular Newfoundland (SFAs 3 to 14A) and the Strait of Belle Isle shore of Labrador (SFA 14B), the daily limits were either one small salmon retained or two fish, caught and released. The season started with a seasonal bag limit of one small salmon and was increased to four small salmon after an in-season review in July. In the northern and southern SFAs of Labrador (SFA 1 and 2), there was a seasonal limit of four fish, only one of which could be a large salmon. In Québec, season and bag limits varied by zone: for Q1 to Q8 and Q10, the season limit was seven fish of any size. For rivers in zone Q9 and Q11, the season limit was 10 fish with daily limits of two fish in Q8, three fish in Q9 and four fish in Q11. In most rivers of zones Q1 to Q7 and Q10, fishing for the day would end if the first fish kept was a large salmon. If the first fish kept was a small salmon, then fishing could continue until a second fish was caught, regardless of the size of the second fish. Seven rivers in Québec were restricted to retention of small salmon only at the start of the season, and this regulation was extended to eleven more rivers after mid-season reviews detected low returns of large salmon (Figure 4.1.1.2).

USA

Angling for sea-run Atlantic salmon in the USA is permitted only in the State of Maine, and in 1998 the sport fishery continued to be restricted to catch and release. Effort, as measured by license sales, declined by 16% in 1998 and was 46% and 53% below the 5- and 10-year averages, respectively.

France (Islands of Saint-Pierre and Miquelon)

For the Saint-Pierre and Miquelon fisheries in 1998, there were nine professional and 42 recreational licenses issued. The number of professional fishermen has decreased slightly since 1995 and the number of recreational licenses has remained about the same.

Year	Number of Professional Fishermen	Number of Recreational Licenses
1995	12	42
1996	12	42
1997	6	36
1998	9	42

4.1.2 Catch and catch per unit effort (CPUE)

Canada

The provisional harvest of salmon in 1998 by all users was 149 t, a decrease of 35% by weight from the 1997 harvest of 229 t (Table 4.1.2.1; Figure 4.1.2.1).

The 1998 harvest was 46,687 small salmon and 13,270 large salmon, a 21% and 49% decrease from the 1997 harvests for small salmon and large salmon, respectively. The dramatic decline in harvested tonnage since 1988 is in large part the result of the reductions in commercial fisheries effort, the closure of the insular Newfoundland commercial fishery in 1992 and the closure of the Labrador commercial fishery in 1998 (Figure 4.1.2.1). These reductions were introduced as a result of declining abundance of salmon.

The 1998 harvest of small and large salmon, by number, was divided among the three user groups in different proportions depending on the province and the fish-size group exploited (Table 4.1.2.1). Newfoundland reported the largest proportion of the total harvest of small salmon and Québec reported the greatest share of the large salmon harvest. Recreational fisheries exploited the greatest number of small salmon in each provinces, accounting for 88% of the total small salmon harvests in eastern Canada. Unlike previous years when commercial fishers took the largest share of large salmon, Aboriginal fisheries accounted for the largest share in 1998 (57% by number). Commercial fisheries harvested 2% (by number) of the total small salmon and 8% of the total large salmon taken in eastern Canada.

Native peoples' fisheries: In many cases, Native peoples' food fisheries harvests in 1998 were less than the allocations. Harvests in 1998 (by weight) were up 22% from 1997 and 17% above the previous 5-year average harvest.

Native peoples' fisheries			
Year	Harvest (t)	% large	
		by weight	by number
1990	31.9	78	
1991	29.1	87	
1992	34.2	83	
1993	42.6	83	
1994	41.7	83	58
1995	32.8	82	56
1996	47.9	87	65
1997	39.4	91	74
1998	47.9	83	63

Recreational fisheries: Harvest in recreational fisheries in 1998 totalled 45,959 small and large salmon, 30% below the previous 5-year average and 7% below the 1997 harvest level (Figure 4.1.2.2). The small salmon harvest of 41,246 fish was a decrease of 27 % from the previous 5-year mean. The large salmon harvest of 4,713 fish was a 48% decline from the previous five-year mean. Small salmon harvests were down 4% and large salmon harvests were down 30% from 1997. The small salmon size group has contributed 86% on average of the total harvests since the imposition of catch-and-release recreational fisheries in the Maritimes and insular Newfoundland (SFA 3 to 14B, 15 to 23) in 1984 (Figure 4.1.2.2).

Recreational catches (including retained and released fish) of small salmon in 1998 were similar or above the 1984 to 1991 mean in most fishing areas of Québec, and the north-east coast and northern peninsula of Newfoundland and throughout Labrador (Figure 4.1.2.3). Small salmon catches were among the lowest observed in the majority of the Maritimes (with the exception of PEI) and in the west and south coasts of Newfoundland. Large salmon catches were among the lowest observed throughout mainland Canada (with the exception of the Gulf shore rivers of Nova Scotia) but were among the highest in the west coast of Newfoundland, (SFA 12, 13, 14A) and Labrador (SFAs 1,2, and 14B). Catches in PEI (SFA 17) were above average but more than 90% of the returns originate from smolt stocking programs.

In 1984, anglers were required to release all large salmon in the Maritime provinces and insular Newfoundland. Changes in the management of the recreational fisheries since 1984 have compromised the use of angling catches as indices of abundance. Therefore, the interpretation of trends in abundance relies mostly on rivers where returns have been estimated or completely enumerated. Caught-and-released fish are not considered equivalent to retained fish and their inclusion in catch statistics further compromises the reliability of interpretation of trends. In more recent years, anglers have been required to release all salmon on some rivers for conservation reasons and, on others, they are voluntarily releasing angled fish. In addition, numerous areas in the Maritimes Region in 1998 were closed to retention of all sizes of salmon (Figure 4.1.1.2).

In 1998, over 50,000 salmon (about 21,000 large and 30,000 small) were caught and released (Table 4.1.2.2), representing about 52% of the total number caught, including retained fish. This was a 4% increase from the number released in 1997, the only other year where there are estimates available for all areas. Most of the fish released were in Newfoundland (45%), followed by New Brunswick (41%), Nova Scotia (7%), Québec (6%) and Prince Edward Island (<1%). Expressed as a proportion of the fish caught, that is, the sum of the retained and released fish, Nova Scotia released the highest percentage (87%), followed by New Brunswick and Newfoundland (56% each), Prince Edward Island (55%) and Québec (22%).

Commercial fisheries: The commercial harvest in 1998 declined to 5 t from a peak of more than 2,400 t in 1980 (Figure 4.1.2.4) with only area Q9 of Québec reporting a commercial harvest. In Québec, the harvest of large salmon in the commercial fishery continued to decline in 1998, as a result of license retirements.

Unreported catches: Canada has been providing estimates of unreported catches of Atlantic salmon since 1986. Until 1997, these numbers have previously been confidential and summed in the Working Group reports either as part of a total for the North Atlantic or as a subset expressed as a total for the North American Commission area. However, it has been obvious that most of the unreported catch estimated for the North American Commission area has been Canada's as based on its much higher reported catch compared to the USA and Sainte-Pierre and Miquelon.

Canada's unreported catch estimate for 1998 is about 91 t, about the same as estimates made for 1997. Estimates were included for all provinces and were provided mainly by enforcement staff. In some cases where enforcement staff did not respond to requests for estimates, values previously provided were assumed for 1998. Most unreported catch arises from illegal retention of salmon.

By stock groupings used for Canadian stocks throughout the report, the unreported catch estimates for 1998 were:

Stock Area	Unreported Catch (t)
Labrador	7.5
Newfoundland	24.5
Gulf	37.8
Scotia-Fundy	1.1
Québec	20.1
Total	91.0

USA

There was no harvest of sea-run Atlantic salmon in the USA in 1998. The estimated number of salmon caught and released was 273 fish, which represented decreases of 18% from the previous year (333 fish) and 32% and 33% from the previous 5- and 10-year averages, respectively. Most of the reduced catch in 1998 occurred in the Penobscot River and was attributed to a decline in salmon abundance, a reduction in the length of the angling season (initiated in 1997), and a reduction in angler effort (as evidenced by reduced license sales). Unreported catches were estimated to be 0 in 1998.

France (Islands of Saint-Pierre and Miquelon)

The harvest in 1998 was reported to be 2.3 t, up from about 1.5 t in 1997 and the largest value since 1994. Professional fishermen harvested 1.0 t and recreational fishermen, 1.3 t in 1998. There was no estimate made of unreported catch for 1998.

4.1.3 Origin and composition of catches

In the past, salmon from both Canada and USA have been taken in the commercial fisheries of Labrador. These fisheries were closed in 1998. The remaining Aboriginal food fisheries that exist in this area may intercept some salmon from other areas of North America although there are no reports of tagged fish being captured there in 1998.

Canada

Origin of returns in 1998: Fish designated as being of wild origin are defined as the progeny of fish where mate selection occurred naturally (eggs not stripped and fertilised artificially) and whose life cycle is completed in the natural environment (ICES 1997/Assess:10). Hatchery-origin fish, designated as fish introduced into the rivers regardless of life stage, were identified on the basis of the presence of an adipose clip, from fin deformations, and/or from scale characteristics. Not all hatchery fish could be identified as such in the returns because of stocking in the early life stages. Aquaculture escapees were identified from hatchery fish on the basis of fin erosion (especially of the tail) and from scale characteristics.

The returns to the majority of the rivers in Newfoundland and to most rivers of the Gulf of St. Lawrence and Québec were comprised exclusively of wild salmon (Figure 4.1.3.1). Hatchery origin salmon made up varying proportions of the total returns and were most abundant in the rivers of the Bay of Fundy and the Atlantic coast of Nova Scotia. Aquaculture escapees were present in the returns to three rivers of the Bay of Fundy (St. Croix, Magaguadavic and Saint John), two rivers of the Gulf of Maine (Dennys and Narraguagus), as well as three rivers (Middle, Baddeck and North) in Cape Breton Island (Table 4.1.3.1).

Aquaculture production of Atlantic salmon in eastern Canada has increased annually, exceeding 10,000 t in 1992 and rising to almost 23,000 t in 1998 (Table 2.2.1.1). Escapes of Atlantic salmon have occurred annually. In 1994, escapes of Atlantic salmon in the Bay of Fundy area were estimated at 20,000 to 40,000 salmon, an amount greater than the total returns of wild and hatchery origin salmon (both small and large) (13,000 to 21,000 fish) to the entire Bay of Fundy and Atlantic coast of Nova Scotia area (SFA 19 to 23) in the same year. The level of escapes in 1993 was similar to that of 1994. Levels of escapes for 1995 to 1998 are unknown.

The proportion of the run that are aquaculture escapees has increased in the Magaguadavic River (SFA 23; Table 4.1.3.1) which is in close proximity to the centre of the aquaculture production area (Figure 4.1.3.2 upper panel; lower panel is historical occurrences). Escaped fish were not observed between 1983 and 1988. Since 1992, escaped fish have comprised between 33% and 90% of the total counts at the fishway. Aquaculture escapees comprised between 13% and 54% of the total run of salmon to the St. Croix River during 1994 to 1998 (Table 4.1.3.1).

USA

Some salmon that were caught in the sport fishery in 1998 may have been escapees from aquaculture operations in Maine and New Brunswick. In addition, a few of those caught and released originated from captive broodstock that were released into four Maine rivers. The incidence of aquaculture escapes was low in 1998, although most Maine rivers in the vicinity of aquaculture operations were not monitored. There were no aquaculture escapees observed in the Narraguagus River in 1998.

4.1.4 Exploitation rates in Canadian and USA fisheries

Canada

In previous years, overall Canadian exploitation rates were calculated as the harvest of salmon divided by the estimated returns to North America. No estimates of returns to Labrador are possible for 1998, as there was no commercial fishery and no information was collected on freshwater escapements. For this reason, exploitation rates cannot be calculated for 1998. Harvests of 46,687 small and 13,270 large salmon were less than those of 1997, substantially in the case of large salmon, and it is expected that exploitation rates decreased from those of 1997 when values were estimated to be between 0.14 and 0.26 for small and 0.15 and 0.25 for large salmon.

USA

There was no exploitation of USA salmon in home waters and no salmon of USA origin were detected in Canadian catches in 1998.

4.2 Status of Stocks in the North American Commission Area

There are approximately 550 Atlantic salmon rivers in eastern Canada and 21 rivers in eastern USA each of which could contain at least one population of salmon. Assessments are prepared for a limited number of specific rivers, because they compose significant fractions of the salmon resource or are indicators of patterns within a region, or

because of the demands by user groups, or as a result of requests for biological advice from fisheries management. The status is evaluated by examining trends in returns and escapement relative to the conservation requirements.

4.2.1 Measures of abundance in monitored rivers

Canada

The returns represent the size of the population before any in-river and estuarine removals. Spawning escapement is determined by subtracting all the known removals, including food fisheries, recreational harvests, broodstock collections, and scientific samples from the total returns.

A total of 90 rivers were assessed in eastern Canada in 1998. Estimates of total returns of small and large salmon were obtained using various techniques: 43 were derived from counts at fishways and counting fences; six were obtained using mark and recapture experiments; 32 using visual counts by snorkeling or from shore; and 9 from angling catches or redd counts.

1998 compared to 1997 adult returns: Of the 90 stocks for which returns of salmon were determined in 1998, comparable data were available for 76 of these in 1997. For 51 of these rivers, returns were estimated by small salmon and large salmon size groups separately in both years (Table 4.2.1.1). For both size groups combined, returns in 1998 were less than 50% of the 1997 returns in three of the 76 rivers assessed (4%), between 50% and 90% of 1997 returns in 41% of the rivers and were 90% or greater than 1997 returns in 55% of the rivers.

Large salmon returns in 1998 decreased from 1997 in rivers throughout the Maritime provinces and Québec but were equally down or improved in Newfoundland (Table 4.2.1.1; Figure 4.2.1.1). In most of the rivers of Newfoundland, except for rivers of the south-west coast (SFA 13), large salmon are mostly repeat-spawning 1SW fish. Small salmon returns in 1998 relative to 1997 were generally improved throughout eastern Canada (Figure 4.2.1.1). Returns were similar to or improved (>90% in 1998 relative to 1997) in 71% of the assessed rivers. The north-west and north-east coast Newfoundland rivers showed the most consistent improvement in returns.

1985-98 patterns of adult returns: Annual returns of salmon by size group are available for 24 rivers in eastern Canada since 1985. These returns do not account for commercial fisheries removals in Newfoundland, Labrador, Québec and Greenland and in some rivers include returns from hatchery stocking. Peak return years differed for regions within eastern Canada (Figure 4.2.1.2). The returns during the Newfoundland commercial fishery moratorium years (1992 to 1998) for all areas except Newfoundland are lower than returns in 1986 to 1988 when there were commercial fisheries in Newfoundland, Labrador, Québec and Greenland harvesting mainland Canada origin salmon. The total returns to six Newfoundland rivers doubled during 1993 to 1996 from the low levels observed during 1989 to 1991 (Figure 4.2.1.2). The returns in-river of small salmon in 1998 were collectively the second highest observed in the time series and the large salmon are the highest recorded.

The returns of large salmon in all areas except Newfoundland were the lowest observed during 1985 to 1998 (Figure 4.2.1.2). Returns of small salmon to six Gulf rivers (NB, NS) in 1998 improved from 1997 but were 44% of the average returns during 1985 to 1991, prior to the Newfoundland commercial fishery moratorium. The returns of large salmon in 1998 were the lowest of the time series at less than 23,000 fish. Returns to the rivers of the Atlantic coast of Nova Scotia and Bay of Fundy declined to new lows for large salmon. Returns to nine rivers of Québec in 1998 were the second lowest since 1985 with large salmon returns declining the most to the lowest since 1985. The low abundance of 2SW salmon was most evident in the Québec and Gulf rivers. Low abundance of 2SW salmon in 1998 had been anticipated from the low abundance of 1SW salmon in 1997.

Smolt and juvenile abundance: Counts of smolts provide direct measurements of the outputs from the freshwater habitat. Previous reports have documented the high annual variability in the annual smolt output: in tributaries, smolt output can vary by five times but in the counts for entire rivers, annual smolt output has generally varied in magnitude by a factor of two. Wild smolt production has been estimated in 11 rivers of eastern Canada, although only nine rivers have several years of data (Figure 4.2.1.4). In other rivers, juvenile abundance surveys have been conducted (Figure 4.2.1.4).

In the Québec rivers where smolt production has been monitored, the 1997 and 1998 smolt productions were less than half the 1990 to 1995 average (Figure 4.2.1.5). The low smolt production in the Québec Zone Q7 was attributed to the July 1996 flood which physically reconfigured a large number of rivers in that zone and resulted in a near complete loss of the juveniles in 1996. In Newfoundland, smolt production in 1996 to 1998 remained above the 1990 to 1995 average in the indexed rivers except for the southwest coast river (Highlands) (Figure 4.2.1.5).

Juvenile salmon abundance has been monitored annually since 1971 in the Miramichi (SFA 16) and Restigouche (SFA 15) rivers and for shorter and variable time periods in other rivers (Figure 4.2.1.4). In the rivers of the southern Gulf,

densities of young-of-the-year (fry) and parr (juveniles of one or more years old) have increased since 1985 in response to increased spawning escapements (Figure 4.2.1.6). Densities of parr in 1998 declined from recent years but remained high relative to the 1970s. In the Restigouche River, both fry and parr densities remain high and near record levels. High densities of juveniles have also been reported from Nova Scotia rivers along the Gulf of St. Lawrence (SFA 18) and in several Cape Breton Island streams (SFA 19). This is in contrast to juvenile densities from an inner Bay of Fundy river (Stewiacke River; SFA 22) which have declined since 1984, as a result of reduced spawning escapement. Densities of juveniles in the Stewiacke River in 1998 were at record low level (Figure 4.2.1.6).

The total number of smolts leaving Canadian rivers is unknown. However, a combination of smolt counts and juvenile abundance indices, considered as surrogates of smolt production, allow development of indices of total smolt production from eastern Canada. To allow for the combined analysis of smolt counts and juvenile abundance surveys from all the rivers, the individual river surveys were standardized by the average within river abundance for the period 1995 to 1998.

$$\text{Ind}_{ij} = \text{Abund}_{ij} / \text{Average}_{ij}$$

where Ind_{ij} = Adjusted index of juvenile or smolt abundance for year i and river j ,
 Abund_{ij} = Measured abundance of juvenile or smolts for year i and river j , and
 Average_{ij} = Average abundance for years i' (1995 to 1998) in river j .

This adjustment places all the rivers on a common scale and provides a measure of the temporal variability in the smolt and juvenile measures. Juvenile measures were age 1 and older parr which were projected forward one year to correspond to the smolt migration year.

The index of smolts from the broader geographic areas of eastern North America (Labrador, Newfoundland, Quebec, Gulf, Scotia-Fundy and U.S.) was obtained by weighting the annual river indices by the relative proportion of the conservation egg requirements (O'Connell *et al.* 1997) of the SFA or Zone to the total conservation egg requirements of the zones under consideration (Table 4.2.1.2). The longest time series are from Western Arm Brook (SFA 14A) in Newfoundland and the Miramichi and Restigouche rivers in the Gulf (SFAs 15 and 16). The number of rivers with available data has increased from two in 1971 to between 19 and 20 rivers in 1995 to 1998. The proportion of the indexed areas represented by the index rivers has increased from 11% in 1971 to 25% in 1998 (Table 4.2.1.3).

The relative change in smolt production or juvenile abundance differs among the three rivers with the longest time series (Figure 4.2.1.7). Smolts from Western Arm Brook peaked in the mid 1980s and again in the mid 1990s. This contrasts with the Miramichi juvenile index which was low through the 1970s to mid 1980s and rose quickly to maximum levels in the 1990s. The Restigouche index has essentially increased continually from 1972 to 1998. The relative index weighted by the area-index proportions suggests relative smolt production at three levels since 1971 - at about one-third the 1995 to 1998 average between 1971 and 1979, at about 60% of the average during 1980 to 1985 and at about average since 1986 (Figure 4.2.1.7). Weighted relative to the index river size, the trend in smolt index is similar to the Miramichi index since this river represents at least 45% of the total river-weight index (Figure 4.2.1.7, Table 4.2.1.2).

Estimates of the relative smolt index in the four geographic areas correspond to the previously documented status of rivers (Figure 4.2.1.8). Smolt production from Newfoundland rivers has approximately doubled over the 1971 to 1998 time period (Figure 4.2.1.8). The Gulf smolt index is at its highest level in the 1990s. The Quebec smolt index has declined between 1983 and 1998, driven by de la Trinité time series which for Quebec has a large area-index weight (Table 4.2.1.2). The relative index for Scotia-Fundy peaked around 1990 and has since declined.

USA

Documented adult salmon returns to rivers in New England in 1998 amounted to 1,745 salmon (Figure 4.2.1.3), which was about the same number observed (1,746) in 1997. Total salmon returns to the rivers of New England continued their downward trend, and were 15% and 37% lower than the previous 5-r and 10-year averages, respectively. Returns of 1SW salmon increased by 13% (310 to 356), while MSW returns declined by 3% (1,436 to 1,389) from the previous year. The documented adult returns are minimal estimates, since many rivers in Maine do not contain counting facilities and all counting facilities throughout New England are less than 100% effective at capturing adult salmon.

Most of the USA salmon returns were recorded in the rivers of Maine, with the Penobscot River accounting for about 69% of the total. Returns to the Penobscot River (1,210 fish) were 11% lower than the previous year, 20% lower than the previous 5-year average and 42% lower than the previous 10-year average.

Adult salmon returns to many other Maine rivers with fish counting facilities were similar to those observed in 1997, although the trap catch of salmon on the Narraguagus River (22 salmon) was the smallest number counted since trapping of salmon began in 1960.

About 17% of the USA returns (300 salmon) were recorded in the Connecticut River, a 51% increase from the previous year. Returns to the Connecticut River in 1998 were 28% and 29% above the previous 5- and 10-year averages, respectively.

Salmon returns to the Merrimack River numbered 123 fish. This represented a 73% increase from the previous year, and increases of 132% and 3% above the previous 5- and 10-year averages, respectively.

4.2.2 Estimates of total abundance by geographic area

For assessment purposes, the following regions were considered: Labrador (SFA 1, 2, & 14B), Newfoundland (SFA 3–14A), Québec (Q1-Q11), Gulf of St. Lawrence (SFA 15-18), Scotia-Fundy (SFA 19-23) and USA. Returns of 1SW and 2SW salmon to each region (Tables 4.2.2.1 and 4.2.2.2; Figures 4.2.2.1 and 4.2.2.2; and Appendix 6) were estimated by updating the methods and variables used by Rago *et al.* (1993b) and reported in ICES 1993/Assess:10. The returns for both sea-age groups were derived using a variety of methods using data available for individual river systems and management areas. These methods included counts of salmon at monitoring facilities, population estimates from mark-recapture studies, and the application of angling and commercial catch statistics, angling exploitation rates, and measurements of freshwater habitat (Appendix 6). MSW returns were proportioned to 2SW returns on the basis of sea-age composition of one or more indicator stocks.

In the context used here "returns" are the number of salmon that returned to the geographic region, including homewater commercial fisheries, except in the case of Newfoundland and Labrador regions where returns do not include commercial fisheries. The addition of catches of Newfoundland and Labrador origin salmon in commercial fisheries in Newfoundland and Labrador to "returns" to Newfoundland and Labrador are referred to as total "recruits". Estimation of "recruits" to Québec, Gulf of St. Lawrence, Scotia Fundy and USA regions are not possible because the origin of intercepted salmon in the Newfoundland-Labrador commercial fisheries are not specifically known. In part this was done to avoid double counting of fish when commercial catches in Newfoundland and Labrador are added to returns of all geographic in North America to create the PFA of North American salmon.

Labrador

The basis for estimates of 2SW and 1SW salmon returns and spawners for Labrador (SFAs 1, 2 & 14B) prior to 1998 are catch data from angling and commercial fisheries. Catch and effort data from the angling fishery were collected by DFO enforcement staff in conjunction with angling reports submitted by fish camp operators and processed by DFO Science Branch personnel. In 1997 for SFA 14B, the angling catch statistics were derived from a licence stub system similar to insular Newfoundland while in SFAs 1 & 2 the camp statistics data were used. Commercial catch data were collected by DFO enforcement staff from fish plant landing slips and processed by DFO Statistics and Informatics Branch personnel.

In 1998, there was no commercial fishery in Labrador and no complete counts exist for any Labrador river in 1998. Hence, it was not possible to estimate the returns or spawners to Labrador for this year.

Newfoundland

The estimates of 1SW and 2SW returns and spawners for insular Newfoundland (SFAs 3–12 & 14A) are updated for 1998. They are derived from exploitation rates estimated from rivers with counting facilities which are subsequently applied to angling catches of small salmon, adjusted for the proportions of large:small salmon at counting facilities, and finally the proportion of large salmon that are 2SW. Exploitation rates for small salmon (retained only) were calculated by dividing the total count and the catch (retained) from rivers with enumeration facilities. In 1998, for SFAs 3–12 and 14A, angling catch data was derived from the licence stub return system (O'Connell *et al.* 1997) while in previous years angling catch data was collected by DFO Fishery Officers and Guardian staff. For SFA 13, returns and spawners come from four assessment facilities expanded to the entire drainage area based on their proportionate contribution.

The mid-point of the estimated returns (187,000) of 1SW salmon to Newfoundland rivers in 1998 is 61% higher than 1997 and 10% lower than the average 1SW returns (170,300) for the period 1992–94 (Figure 4.2.2.1, Appendix 6). The 1992–95 1SW returns are higher than the returns in 1989–91, but similar to the returns to the rivers between 1971 and 1988. The 1SW recruits to Newfoundland, before commercial fisheries, have declined significantly from about 500,000 in 1988 to 187,000 in 1998.

The mid-point (8,000) of the estimated 2SW returns to Newfoundland rivers in 1998 is 60% higher than in 1997 and the highest value in the time series (1971–98) of returns (Figure 4.2.2.2, Appendix 6). The 2SW recruits however in 1998 are similar to 1992–97 and these years are the lowest observed in the time series (1969–98).

Québec

The procedure to estimate returns was revised by using individual river information for 117 rivers for each year between 1984 and 1998 as described last year. The mid-point (31,600) of the estimated returns of 1SW salmon to

Québec in 1998 is a 10% increase from the returns observed in 1997 and a 9 % decrease from the 1992-97 average (Figure 4.2.2.1).

The mid-point (33,700) of the estimated returns of 2SW salmon in Québec in 1998 is a 8% decrease from the returns observed for 1997 and a 25% decrease from the average of the years 1992-97 (Figure 4.2.2.2). Within the 1971-98 time series, the 1998 value is the lowest estimated and continues a downward trend from the high of 98,000 2SW salmon in 1980.

Gulf of St. Lawrence, SFAs 15–18

The mid-point (53,300) of the estimated returns in 1998 of 1SW salmon returning to the Gulf of St. Lawrence was a 31% increase from 1997, however it is the second lowest value since 1984. The low values noted in 1997 and 1998 continue a downward trend from the high value of about 188,000 in 1992 (Figure 4.2.2.1, Appendix 6).

The mid-point (13,700) of the estimate of 2SW returns in 1998 is 50% lower than the estimate for 1997 and the second lowest of the time series (Figure 4.2.2.1, Appendix 6), the lowest being 1979 at 11,500. Returns of 2SW salmon have declined steadily since 1995.

Scotia-Fundy, SFAs 19-23

The mid-point (16,700) of the estimate of the 1SW returns in 1998 to the Scotia-Fundy Region was an 89% increase from the 1997 estimate, which was the lowest value in the time series, 1971-1998. Returns have generally been low since 1990 (Figure 4.2.2.1, Appendix 6).

The mid-point (4,400) of the 2SW returns in 1998 is 9% lower than the returns in 1997 and the lowest value in the time series, 1971–97 (Figure 4.2.2.2, Appendix 6). A declining trend in returns has been observed from 1985 to 1998.

USA

Total salmon returns and spawners for USA rivers in 1998 were calculated as described in ICES 1996/Assess:11. Since harvest of salmon is not permitted in Maine and many rivers do not contain fish counting facilities, run sizes for several small rivers in Maine continue to be underestimated. In recent years, the number of USA spawners is considered to be the same as the number of estimated returns because it is not possible to determine the age and origin of salmon caught in the sport fishery, nor mortality associated with catch-and-release angling in Maine.

The estimated 1SW returns and spawners to USA rivers in 1998 were 403 salmon. This was 10% above the estimated returns in 1997, and 3% and 35% below the previous 5- and 10-year averages, respectively (Table 4.2.2.1, Figure 4.2.2.1).

The estimated 2SW returns and spawners to USA rivers in 1998 was 1,526 salmon. This was 5% below the 1997 estimate, and was 18% and 41% below the previous 5- and 10-year averages, respectively.

North America (combined Canada and USA)

It is not possible to calculate the total numbers of returns in 1998 of either 1SW or 2SW salmon to North America as no estimates exist for Labrador for reasons previously described.

4.2.3 Pre-fishery abundance estimates of non-maturing and maturing 1SW North American salmon

North American run-reconstruction model

The Working Group has used the North American run-reconstruction model to estimate pre-fishery abundance, which serves as the basis of abundance forecasts used in the provision of catch advice. The catch statistics used to derive returns and spawner estimates have been updated from those used in ICES 1998/ACFM:15 (Table 4.2.3.1). The North American run-reconstruction model has also been used to estimate the fishery exploitation rates for West Greenland and in homewaters.

Non-maturing 1SW Salmon

The non-maturing component of 1SW fish, destined to be 2SW returns (excludes 3SW and previous spawners) is represented by the pre-fishery abundance estimator for year i designated as $[NN1(i)]$. Definitions of the variables are given in Table 4.2.3.2. It is constructed by summing 2SW returns in year $i+1$ $[NR2(i+1)]$, 2SW salmon catches in commercial and Aboriginal food fisheries in Canada $[NC2(i+1)]$ and catches in year i from fisheries on non-maturing 1SW salmon in Canada $[NC1(i)]$ and Greenland $[NG1(i)]$.

There are two important changes to the calculations that determine pre-fishery abundance of non-maturing 1SW salmon for 1997. The first change was made because of the inclusion of Aboriginal food harvests of small (AH_s) and large salmon (AH_l) in the reported catches for 1998. As Aboriginal harvests occurred in both Lake Melville and coastal areas of northern Labrador, a new parameter was added to define the fraction of these catches that are immature

(af_imm). This was necessary because non-maturing salmon do not occur in Lake Melville where approximately half the catch originated. However, non-maturing salmon do occur in coastal marine areas in the remainder of northern Labrador. Consequently, af_imm for the fraction of Aboriginal harvests that were non-maturing was set at 0.05 to 0.1 which is half of f_imm from commercial fishery samples. The new equations to calculate NC1 and NC2 are as follows:

$$\text{Eq. 4.2.3.1} \quad \text{NC1}(i) = [(H_s(i)_{\{1-7,14b\}} + H_l(i)_{\{1-7,14b\}} * q) * f_imm] \\ + [(AH_s(i) + AH_l(i) * q) * af_imm], \text{ and}$$

$$\text{Eq. 4.2.3.2} \quad \text{NC2}(i+1) = [H_l(i+1)_{\{1-7,14b\}} * (1-q)] + [AH_l(i+1) * (1-q)]$$

The second change was necessitated by the closure of the commercial fishery in Labrador in 1998. In past reports, salmon returns and spawners for Labrador which make up one of the six geographical areas contributing to NR2 for Canada were based on commercial fishery data. Since the commercial fishery was closed in Labrador in 1998 the time series also ended. However, in order to estimate pre-fishery abundance it was still necessary to include Labrador returns for 1998. Consequently, a raising factor was developed by dividing pre-fishery abundance without Labrador into pre-fishery abundance with Labrador based on the time series of Labrador recruit estimates and pre-fishery abundance data from 1971-96. The raising factor (RFL2) to estimate returns to Labrador for 1998 for 2SW salmon was set to the low and high range of values in the time series which was 1.05 to 1.27. An assumed natural mortality rate [M] of 0.01 per month is used to adjust the back-calculated numbers between the salmon fisheries on the 1SW and 2SW salmon (10 months) and between the fishery on 2SW salmon and returns to the rivers (1 month) as shown below:

$$\text{Eq. 4.2.3.3} \quad \text{NN1}(i) = [\text{RFL2} * ((\text{NR2}(i+1) / \text{S1} + \text{NC2}(i+1)) / \text{S2} + \text{NC1}(i))] + \text{NG1}(i)$$

where the parameters S1 and S2 are defined as $\exp(-M * 1)$ and $\exp(-M * 10)$, respectively. A detailed explanation of the model used to determine pre-fishery abundance is given in Rago *et al.* (1993a).

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for some of the fisheries harvesting potential or actual 2SW salmon. Thus, commercial catches used in the run-reconstruction model for the West Greenland fishery (1993 and 1994), Newfoundland fishery (1992–97) and Labrador fishery (1998) were set to zero in order to remain consistent with catches used in other years in both of these areas (see Section 4.1.1) There were no commercial fisheries in these areas for the years indicated.

As the pre-fishery abundance estimates for potential 2SW salmon require estimates of returns to rivers, the most recent year for which an estimate is available is 1997. The minimum and maximum values of the catches and returns for the 2SW cohort are summarized in Table 4.2.3.3. The 1997 abundance estimates ranged between 69,710 and 126,088 salmon. The mid-point of this range (97,899) is 23% lower than the 1996 value (126,600) and is the lowest in the 26-year time series (Figure 4.2.3.1). The most recent year is shown with hollow symbols as no Labrador values were estimated for this year and the raising factor described previously was used. The results suggest a continuation of the general decline from 807,000 in 1975. The Working Group expressed concern about the continued decline in the pre-fishery abundance and its impact on spawner levels. The low pre-fishery abundance estimates in 1997 are consistent with the low numbers of maturing 1SW salmon in 1997 which came from the same cohort.

Maturing 1SW salmon (grilse)

Estimation of an aggregate measure of abundance has utility for identifying trends, evaluating management measures, and investigating the influence of the marine environment on survival, distribution, and abundance of salmon. Grilse (or maturing 1SW salmon) are in some areas a major component of salmon stocks and measuring their abundance is thought to be important to provide measures of abundance of the entire cohort from a specific smolt class.

For the commercial catches in Newfoundland and Labrador, all small salmon are assumed to be 1SW fish based on catch samples which show the percentage of 1SW salmon to be in excess of 95%. Large salmon are primarily MSW salmon but some maturing and non-maturing 1SW are also present in commercial catches in SFAs 1–7, 14B. Estimates of fractions of non-maturing salmon present in the Newfoundland and Labrador catch were presented in ICES 1991/Assess:12. The “large” category in SFAs 1–7,14B consists of 0.1–0.3 1SW salmon (Rago *et al.* 1993a; ICES 1993/Assess:10). Salmon catches in SFAs 8–14A are mainly maturing salmon (Idler *et al.* 1981). These values were assumed to apply to the Aboriginal food fishery catches in marine coastal areas of northern Labrador.

Similar to calculations to determine non-maturing 1SW salmon, a raising factor was also required to include Labrador returns in the maturing component of pre-fishery abundance necessitated by the closure of the commercial fishery in Labrador in 1998. Consequently, a raising factor was developed by dividing pre-fishery abundance without Labrador into pre-fishery abundance with Labrador based on the time series of Labrador recruit estimates and pre-fishery

abundance data from 1971-97. The raising factor (RFL1) to estimate returns to Labrador for 1998 for 1SW salmon was set to the low and high range of values in the time series which was 1.04 to 1.59.

The component of 1SW fish destined to mature as grilse is represented by the pre-fishery abundance estimator for year i [MN1(i)]. It is constructed by summing maturing 1SW returns in year i [MR1(i)] in Atlantic Canada and catches in year i from fisheries on maturing 1SW salmon in Newfoundland and Labrador [MC1(i)]. An assumed natural mortality rate [M] of 0.01 per month is used to adjust the back-calculated numbers between the fishery on 1SW salmon and returns to the rivers (1 month) as shown below:

$$\text{Eq. 4.2.3.4} \quad \text{MN1}(i) = [\text{MR1}(i) / S1 + \text{MC1}(i)] * \text{RFL1}$$

where the parameter $S1$ is defined as $\exp(-M * 1)$.

$$\begin{aligned} \text{Eq. 4.2.3.5} \quad \text{MC1}(i) = & [(1-f_{\text{imm}})(H_{\text{s}}(i)_{\{1-7,14b\}} + q * H_{\text{l}}(i)_{\{1-7,14b\}})] + H_{\text{s}}(i)_{\{8-14a\}} \\ & + [(1-af_{\text{imm}})(AH_{\text{s}}(i) + q * AH_{\text{l}}(i))] \end{aligned}$$

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for the fisheries harvesting 1SW salmon. Thus, catches used in the run-reconstruction model for the Newfoundland commercial fishery were set to zero for 1992-97 to remain consistent with catches used in other years in this area (see Section 4.1.1).

The minimum and maximum values of the catches and returns for the 1SW cohort are summarised in Table 4.2.3.4 and the mid-point values are shown in Figure 4.2.3.1. The most recent year is shown with hollow symbols as no Labrador values were estimated for this year and the raising factor described previously was used. The mid-point of the range of pre-fishery abundance estimates for 1998 (412,500) is 29% higher than 1997 (319,000) which was the lowest estimated in the time series 1971-97. Estimates for 1995 and 1994 decreased over those of the previous two years. The reduced values observed in 1978 and 1983-84 were followed by large increases in pre-fishery abundance.

Total 1SW recruits (maturing and non-maturing)

Figure 4.2.3.1 shows the pre-fishery abundance of 1SW maturing and 1SW non-maturing salmon from North America for the period 1971 to 1997 and Figure 4.2.3.2 shows these data combined to give the total 1SW recruits. The steady decline in recruits over the last ten years is alarming. Although the declining trend appears common to both maturing and non-maturing portions of the cohort, non-maturing 1SW salmon have declined at a steeper rate. Causes for the differences in rate of decline are uncertain. Figure 4.2.3.1 shows that grilse are becoming an increasingly larger proportion of the total North American stock complex. This proportion has risen from about 45% at the beginning of the 1970s to almost 80% in the last year. The Working Group expressed concerns about these stock trends and recommended further investigation into their causes.

4.2.4 Spawning escapement and egg deposition

Canada

Egg depositions in 1998 exceeded or equalled the river specific conservation requirements in 21 of the 71 assessed rivers (30%) and were less than 50% of conservation in 24 other rivers (34%) (Figure 4.2.4.1). Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where eight of the 12 rivers assessed (67%) had egg depositions which were less than 50% of conservation requirements. Proportionally fewer rivers in Gulf (19%) and Quebec (35%) had egg depositions less than 50% of conservation. Only 25% of the Gulf rivers and 12% of the Quebec rivers had egg depositions which equalled or exceeded conservation (Figure 4.2.4.1). In insular Newfoundland, 71% of the rivers assessed met or exceeded the conservation egg requirements and almost all the others (24%) had egg depositions which were less than 50% of requirement. The deficits occurred in the southwest rivers of Newfoundland (SFA 13).

Nineteen rivers in Newfoundland and Québec are under rehabilitation or colonization programs where in recent years salmon have gained access to previously inaccessible habitat or to re-establish the wild production (Figure 4.2.4.1). Four of these rivers met or exceeded the conservation requirements in 1998. Egg depositions in 79% of these rivers were less than 50% of requirements. Egg depositions in 1998 relative to 1997 were similar or improved in 53% of these rivers.

Escapements over time relative to conservation requirements have improved in some areas of eastern Canada but have declined in others (Figure 4.2.4.2). The status of three Bay of Fundy/Atlantic coast of Nova Scotia rivers has severely declined, especially since 1991. The proportion of the conservation requirements achieved were the lowest in all three rivers in 1998. For the Québec rivers, spawning escapements declined continually from a peak median value in 1988 with a slight recovery in 1995. Escapements relative to conservation were among the lowest in the series with a few rivers showing improvements in 1998. The eight rivers of the Gulf of St. Lawrence have been the most consistent in equalling or exceeding the conservation requirements but the median escapements were below conservation requirements in the last five years. Newfoundland rivers have shown the greatest improvement in the proportion of the spawning requirement achieved as a direct result of the commercial salmon and groundfish moratoria initiated in 1992. There was a decline in 1997 relative to 1996 but escapements increased again in 1998 to their highest median values since the 1992 closure of the commercial salmon fishery.

Run-reconstruction estimates of spawning escapement

Updated estimates for 2SW spawners were derived for the six geographic regions referenced in Section 4.2.2 (Table 4.2.4.1). Estimates of 1SW spawners, 1971-98 are provided in Table 4.2.4.2. These estimates were derived by subtracting the in-river removals from the estimates of returns to rivers. A comparison between the numbers of spawners, returns and spawning requirements for 1SW and 2SW salmon are shown in Figures 4.2.2.1 and 4.2.2.2 respectively (there are no spawning requirements defined specifically for 1SW salmon).

Labrador: As previously explained, it was not possible to estimate spawners in Labrador in 1998 due to lack of assessment information.

Newfoundland: The mid-point of the estimated numbers of 2SW spawners (8,000) in 1998 is 60% higher than that estimated in 1997 and is 198% of the total 2SW spawner requirements for all rivers. This year is the fifth time that the 2SW spawner requirement has been met or exceeded since 1984 (Figure 4.2.2.2). The 1SW spawners in 1998 increased by 73% from 99,000 in 1997 to 170,900 in 1998. The 1992-96 and 1998 1SW spawners are higher than the spawners in 1989-91 and similar to levels in the late 1970s and 1980s (Figure 4.2.2.1). The spawning level in 1997 however was the third lowest in the data series, with 1989 and 1991 being lower. There had been a general increase in both 2SW and 1SW spawners during the period 1992-96 and 1998 and this is consistent with the closure of the commercial fisheries in Newfoundland. For 1997, decreases occurred most strongly in the 1SW spawners.

Québec: The mid-point of the estimated numbers of 2SW spawners (17,000) in 1998 is lower (6%) than that estimated in 1997 and is about 28 % of the total 2SW spawner requirements for all rivers (Figure 4.2.2.2). The spawning escapement in 1998 is the third lowest in the time series (1971-98) and the lowest since 1979. Estimates of the numbers of spawners have consistently been about one-third to three-quarters of the spawner requirement over the time series (1971-98). The mid-point of the estimated 1SW spawners in 1998 (20,500) was an 11% increase from 1997 (Figure 4.2.2.1). Spawning escapement of 1SW fish has generally been higher since the early 1980s than it was before this period.

Gulf of St. Lawrence: The mid-point of the estimated numbers of 2SW spawners (11,300) in 1998 is 55% lower than that estimated in 1997 and is about 37% of the total 2SW spawner requirements for all rivers in this region (Figure 4.2.2.2). This is the third time in nine years that these rivers have not exceeded their 2SW spawner requirements. The mid-point of the estimated spawning escapement of 1SW salmon (29,600) increased by 21% from 1997 and is the sixth lowest in the time series, 1971-98; the trend has been downwards since the peak of about 153,000 reached in 1992 (Figure 4.2.2.1). Spawning escapement has on average, however, been higher since the mid-1980s than it was before this period.

Scotia-Fundy: The mid-point of the estimated numbers of 2SW spawners (4,000) in 1998 is a 4% decrease from 1997 and is about 16 % of the total 2SW spawner requirements for rivers in this region (Figure 4.2.2.2). Neither the spawner estimates nor the spawner requirements include rivers of the inner Bay of Fundy (SFA 22 and parts of SFA 23) as these rivers do not contribute to distant water fisheries and spawning escapements are extremely low. The 2SW spawning escapement in the rest of the area has been generally declining since 1985. The mid-point of the estimated 1SW spawners (16,200) in 1998 is a 108% increase from 1997 and is the eighth lowest in the time series, 1971-98. There has been a general downward trend in 1SW spawners since 1990 (Figure 4.2.2.1).

Canada: It is not possible to calculate the total numbers of spawners in 1998 of either 1SW or 2SW salmon to North America as no estimates exist for Labrador for reasons previously described.

USA

The estimated 2SW returns (1,526 salmon) to USA rivers in 1998 represents about 5% of the spawner requirements for all rivers. Estimated spawning escapements in the Penobscot, Connecticut and Merrimack rivers remained at very low levels (about 10% for the Penobscot River spawning requirement, and about 2% of requirements established for the Connecticut and Merrimack rivers).

Escapement variability in North America

The projected numbers of potential 2SW spawners that could have returned to North America in the absence of fisheries can be computed from estimates of the pre-fishery abundance taking into consideration the 11 months of natural mortality at 1% per month. These values, termed potential 2SW recruits, along with total North American 2SW returns, spawners and requirements are shown in Figure 4.2.4.3 and indicate that the overall North American spawner requirement could have been met, in the absence of all fisheries, in all years except 1993 to 1998. The difference between the potential 2SW recruits and actual 2SW returns reflect the extent to which mixed stock fisheries at West Greenland and in SFAs 1–14 have reduced the populations.

Similarly, the impact of the Greenland fishery can be considered by subtracting the non-maturing 1SW salmon (accounting for natural mortality) harvested there from the total potential 2SW recruits. These values, termed 2SW recruits to North America, are also shown in Figure 4.2.4.3. The difference between the 2SW recruits to North America and the 2SW returns reflects the impact of removals by the commercial fisheries of Newfoundland and Labrador. The 2SW recruits to North America indicate that, even if there had not been a West Greenland commercial fishery, spawner requirements could not have been met since 1990. The difference between the actual 2SW returns and the spawner numbers reflects in-river removals throughout North America and coastal removals in Québec, Gulf and Scotia Fundy regions.

In 1994, the Working Group (ICES 1994/Assess:16) undertook a preliminary analysis of the effects of escapement on potential fishery yield. It was noted that the stock-recruitment relationship ultimately defines the sustainable level of harvesting and its expected variability over time, although spawning stock size is often not a significant variable in models relating recruitment to stock and environmental variables. The establishment of strong correlations between recruits and an environmental variable is sometimes used to support the notion that spawning stock size is unimportant. However, it was concluded that if environmental variability regulates survival in a density-independent fashion, then the importance of stock size is enhanced.

Following on the technique outlined in previous reports (ICES 1994/Assess:16, ICES 1995/Assess:14), the spawners in each geographic area were allocated (weighted forward) to the year of the non-maturing 1SW component in the Northwest Atlantic using the weighted smolt age proportions from each area (Table 4.2.4.3). The total spawners for a given recruitment year in each area is the sum of the lagged spawners. Because the smolt age distributions in North America range from one to six years and the time series of estimated 2SW spawners to North America begins in 1971, the first recruiting year for which the total spawning stock size can be estimated is 1979 (although a value for 1978 was obtained by leaving out the 6-year old smolt contribution which represents 4% of the Labrador stock complex (Table 4.2.4.3)). Since the 1998 2SW spawners to North America (except for Labrador) are known, the spawning stock contributing to the pre-fishery abundance up to 2001 is known for North America and up to 2002 except for Labrador (Figure 4.2.4.4, Table 4.2.4.4).

Spawning escapement to several stock complexes has been below the spawner requirement (Labrador, Québec, Scotia-Fundy, USA) 1980s (Figure 4.2.4.4). In the last four years, lagged spawner abundance has been increasing in Labrador and Newfoundland but decreasing in all other areas. The relative contributions of the stocks from geographic area to the total spawning escapement of 2SW salmon has varied over time (Figure 4.2.4.5). The reduced potential contribution of Scotia-Fundy stocks and the increased proportion of the spawning stock from the Gulf of St. Lawrence and recently Labrador rivers to future recruitment is most evident. Thus production of non-maturing 1SW salmon would not be expected to increase dramatically from most areas of North America even if the sea survival improves. Only the Gulf and Newfoundland stock complexes have received spawning escapements which have exceeded the area requirements, all other complexes were below requirement and some declined further in 1998.

4.2.5 Survival indices

Canada

Counts of smolts and adult salmon returns enable estimates of marine survival to be derived. Examination of trends over time provide insight into the impact of changes in management measures or other factors that can influence the production of salmon. Information from 13 rivers in Atlantic Canada with smolt counts and corresponding adult counts are available; four are hatchery stocks and ten are wild populations. Geographically, populations for which data were available for the 1998 adult returns ranged from the Saint John River (SFA 23 Bay of Fundy) in the south, LaHave River (SFA 21) and Liscomb River (SFA 20) along the Atlantic coast of Nova Scotia, Saint-Jean (Q2) in the Gaspé region, de la Trinité and aux Rochers (Q7) on the Québec North Shore, and several populations from southern (SFAs 9 and 11), and eastern and northern Newfoundland (SFA 4, 14). In general, survival of hatchery stocks is lower and more variable than that of wild.

There was a large decline in the return rates of both hatchery and wild smolts as 1SW salmon in 1997. The decline was generally observed throughout eastern Canada. Survival rates to the river as 1SW salmon improved for most rivers of

eastern Canada in 1998 relative to survival rates observed in 1997 (Figure 4.2.5.1 to 4.2.5.3). Survival rates to 1SW salmon of hatchery smolts in 1998 were less than 1% while survival rates to 2SW salmon have been less than 0.3% in the recent five years (Figure 4.2.5.1).

In 1998, the survival rate to 1SW salmon was greatly improved from 1997 in de la Trinité River but remained well below the rates observed during the late 1980s (Figure 4.2.5.2). The LaHave River smolt survivals to 1SW salmon improved in 1998 relative to 1997 and were twice those observed for the Québec rivers. The survivals to 2SW salmon in the Quebec rivers declined in 1998 to the lowest levels of the time series (Figure 4.2.5.2).

Following a brief period of increasing survival of smolts in recent years, return rates to most rivers of Newfoundland exhibited a substantive decline in 1997 but generally recovered in 1998 (Figure 4.2.5.3). Considering that the historical survival rates (prior to 1992) represent survival to the river after commercial fisheries, the recent survival rates and in particular the low rates in 1997 are dismal. The survival rates declined in the south (SFA 9, 10) and southwest coast (SFA 13) rivers of Newfoundland and remained at near record low levels. Despite major changes to fisheries and corresponding reductions in marine exploitation, marine survival rates are still low and sea survival of the salmon populations from eastern Canada has not increased as expected.

The Working Group noted that induced freshwater habitat constraints were substantial in some areas and productive capacity has been reduced. Causes include physical, chemical and biological induced constraints. Documented losses include hydropower development, acidification, and siltation. Suspected losses include interactions caused by the introduction of competitive or predator species, chemicals that disrupt endocrine development and localized effects associated with aquaculture. Mitigation of these losses has, for the most part, been insufficient. Fish passage is not generally complete, hatchery production has not generally replaced the loss of natural production, the reduction in atmospheric pollutants has not declined and numbers of suspected negative factors and sites has continued to increase.

Fish passage efficiency, both upstream and downstream, limit populations at hydropower facilities such as on the Saint John River, St. Croix River, and several US rivers. The distribution of endocrine disrupting chemicals has been reduced in some forest spraying programs but these chemicals may also be associated with industrial and municipal wastes and agricultural practises. Aquaculture has continued to increase and documented negative interaction with wild salmon stocks has occurred. Salmon populations of the Southern Uplands of Nova Scotia have fallen to critically low levels in acid-impacted areas while the frequency and duration of acid episodes has increased.

Collectively these factors have reduced the productive capacity of North American salmon populations but cannot account for the decline in adult returns in recent years.

USA

The survival of hatchery-reared smolts released in the Penobscot River in 1996 was 0.18%. This was the second lowest survival observed in the time series (Figure 4.2.5.4), and was 22% and 44% lower than the 5- and 10-years averages, respectively.

4.2.6 Summary of status of stocks in the North American Commission Area

The North American run-reconstruction model was used to update the estimates of pre-fishery abundance of non-maturing and maturing 1SW salmon from 1971–98. The estimate of pre-fishery abundance of 97,899 for 1997 of **non-maturing** 1SW salmon was the lowest on record, and 23% below the previous year. Similarly, for **maturing** 1SW salmon, there was a 32% decrease from 1996 in the 1997 estimate (319,065) of pre-fishery abundance. An estimate of 412,480 maturing 1SW fish in 1998 is 29% greater than that of 1997 and the sixth lowest in the 28-year time series. The results suggest a continuing decline of North American adult salmon abundance. In addition to the steady decline in total recruits over the last 10 years, grilse have become an increasingly larger proportion of the total North American stock complex. This proportion has risen from about 45% at the beginning of the 1970s to between 65 and 80% in the last five years.

The rank of the estimated returns in 1998 in the 1971–98 time series for six regions in North America is shown below:

Region	Rank of 1998 returns in 1971-98 time series (1=highest)		Mid-point estimate of 2SW spawners as proportion of escapement requirement (%)
	1SW	2SW	
Labrador	Unknown	Unknown	unknown
Newfoundland	9	1	198
Québec	13	28	28
Gulf	22	27	37
Scotia-Fundy	23	28	16
USA	13	22	5

In most regions the returns of 2SW fish are near the lower end of the 28-year time series except Newfoundland where they are at the highest level. Returns of 1SW salmon were at the lower end of the time series in Gulf and Scotia-Fundy, and about at the mid-point in Newfoundland, Quebec and USA.

The text table above also shows the estimated total spawning escapement of 2SW salmon in each region expressed as a percentage of the spawning escapement requirement. Only in Newfoundland were requirements exceeded in 1998. The overall 2SW spawning escapement requirement for Canada could have been met or exceeded in only three (1974, 1977 and 1980) of the past 28 years (considering the mid-points of the estimates) by reduction of in-river fisheries (Figure 4.2.4.3). In the remaining years, spawning requirements could not have been met even if all in-river harvests had been eliminated.

The total population of 1SW and 2SW Atlantic salmon in the northwest Atlantic has oscillated around a generally declining trend since the 1970s, and the abundance recorded in 1993–98 was the lowest in the time series (Figure 4.2.3.2). During 1993 to 1997, the total population of 1SW and 2SW Atlantic salmon was about one-half million fish, 45% of the average abundance during 1972 to 1990. The decline has been more severe for the 2SW salmon component than for the small salmon (maturing as 1SW salmon) age group.

Substantive increases in spawning escapements in recent years in northeast coast Newfoundland rivers and high smolt and juvenile production in many rivers, in conjunction with suitable ocean climate indices were suggestive of the potential for improved adult salmon returns for 1998. Colder oceanic conditions both nearshore and in the Labrador Sea in the early 1990s are thought to have contributed to lower survival of salmon stocks in eastern Canada during that period. It was expected that increased marine water temperatures in 1994 to 1997 would have favoured marine survival and subsequent adult salmon production, however, low grilse returns in 1997 provided a strong signal for low returns of 2SW salmon in 1998.

Trends in abundance of small salmon and large salmon within the geographic areas show a general synchronicity among the rivers. Returns of large salmon were generally the lowest observed since 1987 while grilse returns improved marginally for stocks in many areas. For the rivers of Newfoundland, large salmon returns were among the highest in the last 12 years but large salmon returns in the Gulf of St. Lawrence and Québec were among the lowest. The differences in the relative abundance of large salmon in Newfoundland as compared with the other areas of eastern Canada are consistent with the age structure. Large salmon in Newfoundland are predominantly repeat-spawning 1SW salmon while in other areas of eastern Canada, 2SW and 3SW salmon make up varying proportions of the returns.

The continuing absence of any clear factor(s) to explain the lower 1SW returns in 1997 and the low 2SW returns in 1998 make any predictions of river-specific abundance of small and large salmon in eastern Canada in 1999 very uncertain. An additional concern is the low abundance levels which currently describe many salmon stocks in rivers in eastern Canada, particularly in the Bay of Fundy and Atlantic coast of Nova Scotia, and the south coast of Newfoundland. Despite major changes in fisheries management, returns have continued to decline in these areas and many populations are currently threatened with extirpation. Although no direct evidence yet exists that can conclusively indicate that predators are the cause of salmon declines, increasing numbers of predators, particularly seals and seabirds, at the same time that marine survival is declining, suggests that there is a strong possibility that predators and salmon populations are linked (see Section 2.4.6 and 2.4.10, as well as last year's report).

USA salmon stocks exhibit the same downward trend that has been shown for many Canadian salmon stocks, especially those located in the Bay of Fundy and along the Atlantic coast of Nova Scotia. Most salmon rivers in the USA are hatchery-dependent and remain at low levels compared to conservation requirements.

The Working Group noted that induced freshwater habitat constraints were substantial in some areas and productive capacity has been reduced. Causes include physical, chemical and biological induced constraints. Documented losses include hydropower development, acidification, and siltation. Suspected losses include interactions caused by the

introduction of competitive or predator species, chemicals that disrupt endocrine development and localized effects associated with aquaculture.

4.3 Effects on US and Canadian Stocks and Fisheries of Quota Management and Closure after 1991 in Canadian Commercial Salmon Fisheries

There were no new analyses available to the Working Group. Previously, to evaluate the results of the reductions and closures in these commercial fisheries, the Working Group considered a detailed assessment of the impact of the Newfoundland-Labrador changes on Newfoundland stocks (ICES 1997/Assess:10). At that time, estimates were made of commercial exploitation rates on small salmon during premoratorium years (1984-91) which ranged from 29% to 66%, averaging 49% for all areas combined. On large salmon, they ranged from 64% to 98% and averaged 76%.

4.4 Update of Age-Specific Stock Conservation Limits

No new information was available to the Working Group to revise the 2SW salmon conservation requirements for North American rivers, although as indicated in Section 2.4.7, conservation requirements for Québec will be revised next year.

The Working Group recommends that return estimates for the few rivers (Annapolis, Cornwallis and Gaspereau) in SFA 22 that do contribute to distant fisheries be developed and, when these are available, the SFA 22 spawning requirements for these rivers (476 fish) be included in the total.

Spawner requirements for 2SW salmon for Canada now total 154,653 and for the USA, 29,199 for a combined total of 183,852 (Table 4.4.1). The Working Group again recommends that these requirements be refined as additional information on sea-age composition of spawners becomes available and as further understanding of life history strategies is gained.

4.5 Catch Options or Alternative Management Advice and Assessment of Risks Relative to the Objective of Exceeding Stock Conservation Limits

Overview

This is the third year that the Working Group has been asked to provide catch options for the North American Commission Area. Catch options are provided only for the non-maturing 1SW and maturing 2SW components which migrate between two Commission areas and the waters of two, three or four nations. The maturing 1SW component (grilse) is of a lesser migrational tendency, and in the absence of significant marine interceptory fisheries, managed in homewaters by the producing nations.

Catch histories of salmon exposed to the Greenland fishery, 1972-98, are provided in Tables 4.5.1 and 4.5.2. and expressed as 2SW salmon equivalents. The Newfoundland-Labrador commercial fisheries have historically harvested both maturing and non-maturing 1SW salmon as well as 2SW maturing salmon. The harvest in these fisheries of repeat spawners and older sea-ages has not been considered in the run reconstructions. Harvests of 1SW non-maturing salmon in Newfoundland-Labrador commercial fisheries have been adjusted by natural mortalities of 1% per month for 11 months and 2SW harvests in these same fisheries have been adjusted by one month to express all harvests as 2SW equivalents in the year and time they would reach rivers of origin. Starting in 1998, the Labrador commercial fishery was closed. An Aboriginal food fishery occurred in 1998 which may have harvested, to some degree, mixed stocks and catches for this fishery have been included in Tables 4.5.1 and 4.5.2. Mortalities (principally in fisheries) in mixed stock and terminal fisheries areas in Canada are summed with those of USA to estimate total 2SW equivalent mortalities in North America (Table 4.5.1). Mortalities within North America peaked at about 382,000 in 1976 and are now about 23,100 2SW salmon equivalents. In the most recent three years estimated, those taken as non-maturing fish in Labrador comprise about 5% of the total in North America.

The percentage of the cohort destined to be 2SW salmon which were taken in terminal fisheries during 1972-97 in Canada and the USA has ranged from as low as 19% in 1973, 1976 and 1987 to values of 76-85% in 1996-98 fisheries (Table 4.5.1). The percentage increased significantly with the reduction and closures of the Newfoundland and Labrador commercial fisheries, particularly since 1992.

Table 4.5.2 shows the mortalities expressed as 2SW equivalents in Canada, USA and Greenland for 1972-98. Harvests within the USA of the total within North America approached 0.6 % on a few occasions in the time series and as recently as in 1990. As well as these harvests in the USA, USA-origin salmon were also harvested in Canada during the time period indicated. The percentage of the total 2SW equivalents that has been taken in North American waters has ranged from 43-100%, with the most recent year estimated at 67%. The two years when 100 % of the mortality occurred in North America were the years when the Greenland commercial fishery did not operate.

It is possible to provide catch advice for the North American Commission area for two years. The revised forecast for 1999 for 2SW maturing fish is based on a new forecast of the 1998 pre-fishery abundance and accounting for fish which were already removed from the cohort by fisheries in Greenland and Labrador in 1998 as 1SW non-maturing fish. The second is a new estimate for 2000 based on the pre-fishery abundance forecast for 1999 from Section 5.6. A consequence of these annual revisions is that the catch options for 2SW equivalents in North America may change compared to the options developed the year before.

4.5.1 Catch advice for 1999 fisheries on 2SW maturing salmon

A revised forecast of the pre-fishery abundance for 1998 is provided in Table 5.6.1.1. This value of 99,956 is lower than the value forecast last year at this time of 113,899 (See Section 5.2 for more detailed derivation of the models used, etc.). A pre-fishery abundance of 99,956 in 1998 can be expressed as 2SW equivalents by considering natural mortality of 1% per month for 10 months (a factor of 0.904837), resulting in 90,444 2SW salmon equivalents. There have already been harvests of this cohort as 1SW non-maturing salmon in 1998 for both the Labrador (239) and Greenland (11,345) fisheries (Tables 4.5.1 and 4.5.2) for a total of 11,584 2SW salmon equivalents already harvested. The text table below uses the probability density projections for the revised pre-fishery abundance estimate of 99,956 and subtracts the spawning reserve (205,230), converts it to 2SW salmon equivalents and then subtracts the 11,584 2SW equivalents already harvested (Tables 4.5.1 and 4.5.2). The calculation is as follows:

$[(PFA_i - \text{spawning reserve}) \times \exp - (0.01 \times 10 \text{ months})] - \text{harvest in Greenland and Labrador in 1998 of 1SW non-maturing fish}$

where PFA_i = values from 25–90%
 spawning reserve = 205,230
 harvests WG = 1SW non-maturing in 2SW equivalents

Catch Options for 1999 North American Fisheries (Probability levels refer to probability density function estimates of pre-fishery abundance)		
Probability Level	Pre-fishery Abundance Forecast	Catch Options in 2SW Salmon Equivalents (no.)
25	16,337	0
30	34,995	0
35	52,277	0

95	304,286	78,046

4.5.2 Catch advice for 2000 fisheries on 2SW maturing salmon

The text table below, as an example, assumes a 40% Greenland/60% North America division of the surplus for harvest (after reserving the spawner requirement of 205,230) and expresses catch options as 2SW salmon equivalents for 2000 (by considering 10 months of mortality at 1% per month, a factor of 0.904837). As is noted in Section 5.2, there is a wide variability in the forecast and caution is warranted in the use of the 50% level. Precautionary approaches would utilise probabilities much lower than 50%. The calculation is as follows:

$[(PFA_i - \text{spawning reserve}) \times \exp - (0.01 \times 10 \text{ months}) \times 0.60]$

Catch Options for 2000 North American fisheries (probability levels refer to probability density function estimates of pre-fishery abundance)		
Probability Level	Pre-fishery Abundance Forecast	Catch Options in 2SW Salmon Equivalents (no.)
25	795	0
30	18,398	0
35	34,579	0
40	49,917	0
45	64,810	0
50	79,450	0
55	94,097	0
60	108,959	0
65	124,344	0
70	140,537	0
75	158,302	0
80	177,300	0
85	200,047	0
90	229,030	12,921
95	272,057	36,281

The above table provides catch options for 2000 which can be refined next year when information becomes available from harvests of the cohort as non-maturing fish in Greenland and Canada in 1999.

It should be clear from the above that the numbers provided for catch options refer to the composite North American fisheries. As the biological objective is to have all rivers reaching their conservation requirements, it is obvious that river-by-river management is necessary. On individual rivers, where spawning requirements are being achieved, there are no biological reasons to restrict the harvest.

4.6 Data Deficiencies and Research Needs in the North American Commission Area

While some progress was made on research needs identified last year, particularly in the areas of refinement of spawner requirements and the initiation of some wild smolt sampling programs, the Working Group felt that further work is required, and accordingly reiterates last year's recommendations and suggests some further ones.

1. There is an urgent need to monitor salmon returns and develop habitat-based spawner requirements in Labrador and Ungava regions of Québec.
2. There is a need to investigate changes in the biological characteristics (mean weight, sex ratio, sea-age composition) of returns to rivers, spawning stocks, and total recruits prior to fisheries. These data and new information on measures of habitat and stock recruitment are necessary to reevaluate existing estimates of spawner requirements in Canada and USA.
3. There is a requirement for additional smolt-to-adult survival rates for wild salmon. As well, sea survival rates of wild salmon from rivers stocked with hatchery smolts should be examined to determine if hatchery return rates can be used as an index of sea survival of wild salmon elsewhere.
4. Further basic research is needed on the spatial and temporal distribution of salmon and their predators at sea to assist in explaining variability in survival rates.

Table 4.1.1.1. Licensed effort, quota, harvests and percent of total harvest comprised of large salmon in the Labrador and Québec commercial fisheries, 1992 to 1998. The commercial fishery in SFA 14B of Labrador was closed in 1997. A commercial byback was in effect in Labrador in 1998. The commercial fishery in Québec Zone Q7 was closed in 1993 and in Zone Q8 in 1994. A voluntary commercial buyback was in effect in Québec Zone Q9 in 1998.

Table 4.2.3.2 Definitions of key variables used in continental run-reconstruction models for North American salmon.

VARIABLE	DEFINITION
i	Year of the fishery on 1SW salmon in Greenland and Canada
M	Natural mortality rate (0.01 per month)
t1	Time between the mid-point of the Canadian fishery and return to river = 2 months
S1	Survival of 1SW salmon between the homewater fishery and return to river $\{\exp(-M t1)\}$
H _s (i)	Number of “Small” salmon caught in Canada in year i; fish <2.7 kg
H _l (i)	Number of “Large” salmon caught in Canada in year i; fish ≥2.7 kg
AH _s	Aboriginal harvest of small salmon in northern Labrador
AH _l	Aboriginal harvest of large salmon in northern Labrador
f _{imm}	Fraction of 1SW salmon that are immature, i.e. non-maturing; range = 0.1 to 0.2
af _{imm}	Fraction of 1SW salmon that are immature in native fisheries in N Labrador
q	Fraction of 1SW salmon present in the large size market category; range = 0.1 to 0.3
MC1(i)	Harvest of maturing 1SW salmon in Newfoundland and Labrador in year i
i+1	Year of fishery on 2SW salmon in Canada
MR1(i)	Return estimates of maturing 1SW salmon in Atlantic Canada in year i
NN1(i)	Pre-fishery abundance of non-maturing 1SW + maturing 2SW salmon in year i
NR(i)	Return estimates of non-maturing + maturing 2SW salmon in year i
NR2(i+1)	Return estimates of maturing 2SW salmon in Canada
NC1(i)	Harvest of non-maturing 1SW salmon in Nfld + Labrador in year i
NC2(i+1)	Harvest of maturing 2SW salmon in Canada
NG(i)	Catch of 1SW North American origin salmon at Greenland
S2	Survival of 2SW salmon between Greenland and homewater fisheries
MN1(i)	Pre-fishery abundance of maturing 1SW salmon in year I
RFL1	Labrador raising factor for 1SW used to adjust pre-fishery abundance
RFL2	Labrador raising factor for 2SW used to adjust pre-fishery abundance

Table 4.2.3.3. Run reconstruction data inputs and estimated pre-fishery abundance for non-maturing 1SW salmon (potential 2SW salmon) of North American origin (terms defined in Table 4.2.3.2).

Labrador : SFAs 1,2&14B

Newfoundland: SFAs 3-14A

Gulf of St. Lawrence: SFAs 15-18

Scotia-Fundy: SFAs 19-23 (SFA 22 and a portion of SFA 23 are not included as they do not produce 2SW salmon)

Quebec: Q1-Q11

Table 4.2.4.3. Smolt age distributions in six stock areas of North America used to weight forward the spawning escapement in the current year to the year of the non-maturing 1SW component in the Northwest Atlantic.

Stock area	Smolt age (years)					
	1	2	3	4	5	6
Labrador	0.0	0.0	0.077	0.542	0.341	0.040
Newfoundland	0.0	0.041	0.598	0.324	0.038	0.0
Québec	0.0	0.058	0.464	0.378	0.089	0.010
Gulf of St. Lawrence	0.0	0.398	0.573	0.029	0.0	0.0
Scotia-Fundy	0.0	0.600	0.394	0.006	0.0	0.0
USA	0.377	0.520	0.103	0.0	0.0	0.0

Table 4.2.4.4 The mid-point of 25W spawners and lagged spawners for North America and to each of the geographic areas. Lagged refers to the allocation of spawners to the year in which they would have contributed to the year of prefishery abundance.

NF-Lab comm as 1SW = NC1(mid-pt) * 0.904837

NF-Lab comm as 2SW = NC2 (mid-pt) * 0.99005

Terminal fisheries = 2SW returns (mid-pt) - 2SW spawners (mid-pt)

a - starting in 1993, includes estimated mortality of 10% on hook and released fish

b - starting in 1998, there was no commercial fishery in Labrador; numbers reflect size of aboriginal fish harvest in 1998

Figure 4.1.1.1. Map of Salmon Fishing Areas (SFAs) and Quebec Management Zones (Qs) in Canada.

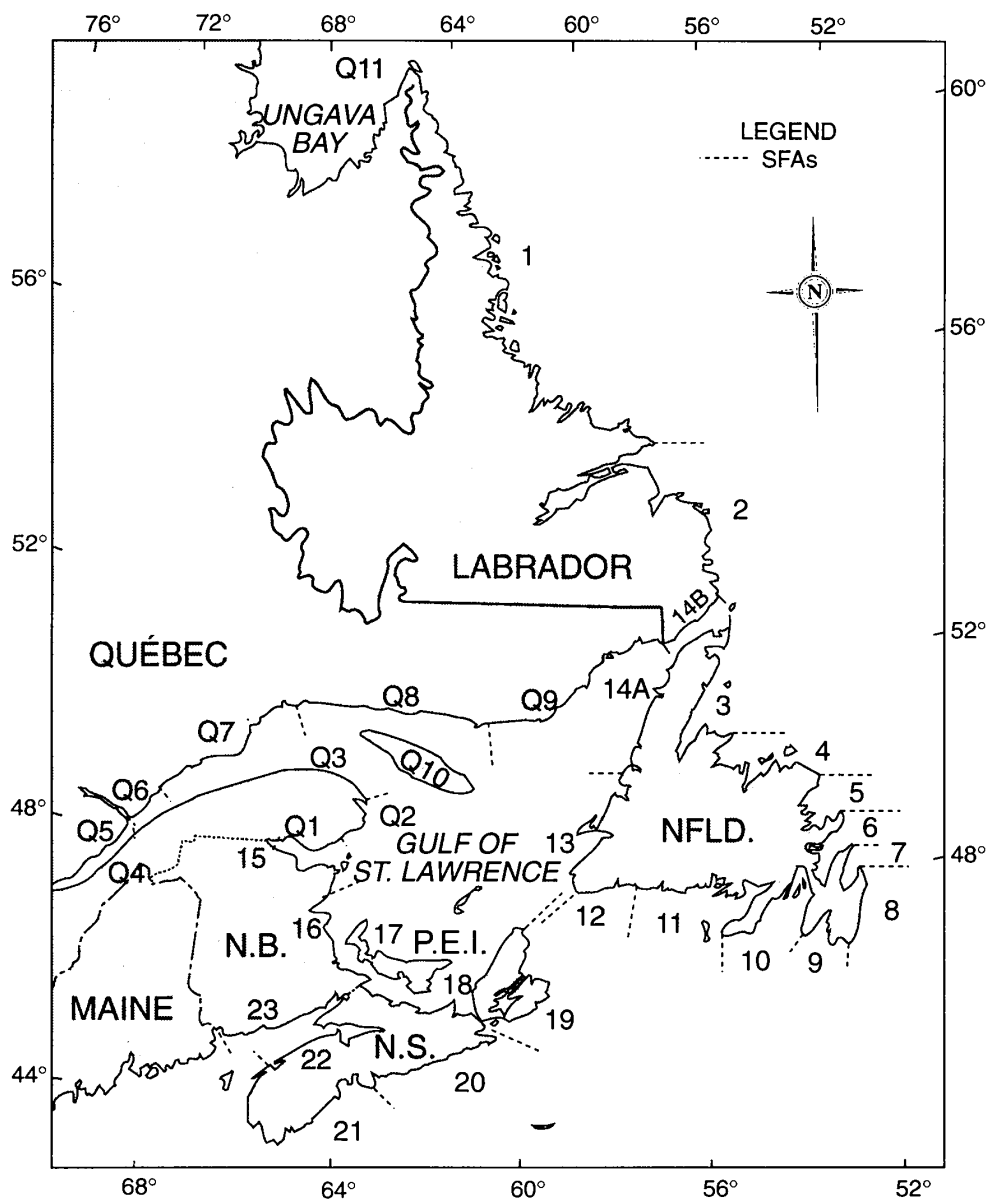

Figure 4.1.1.2. Summary of recreational fisheries management in eastern Canada at the start of the angling season (upper map) and after adjustments stemming from river/area specific inseason assessments during 1998.

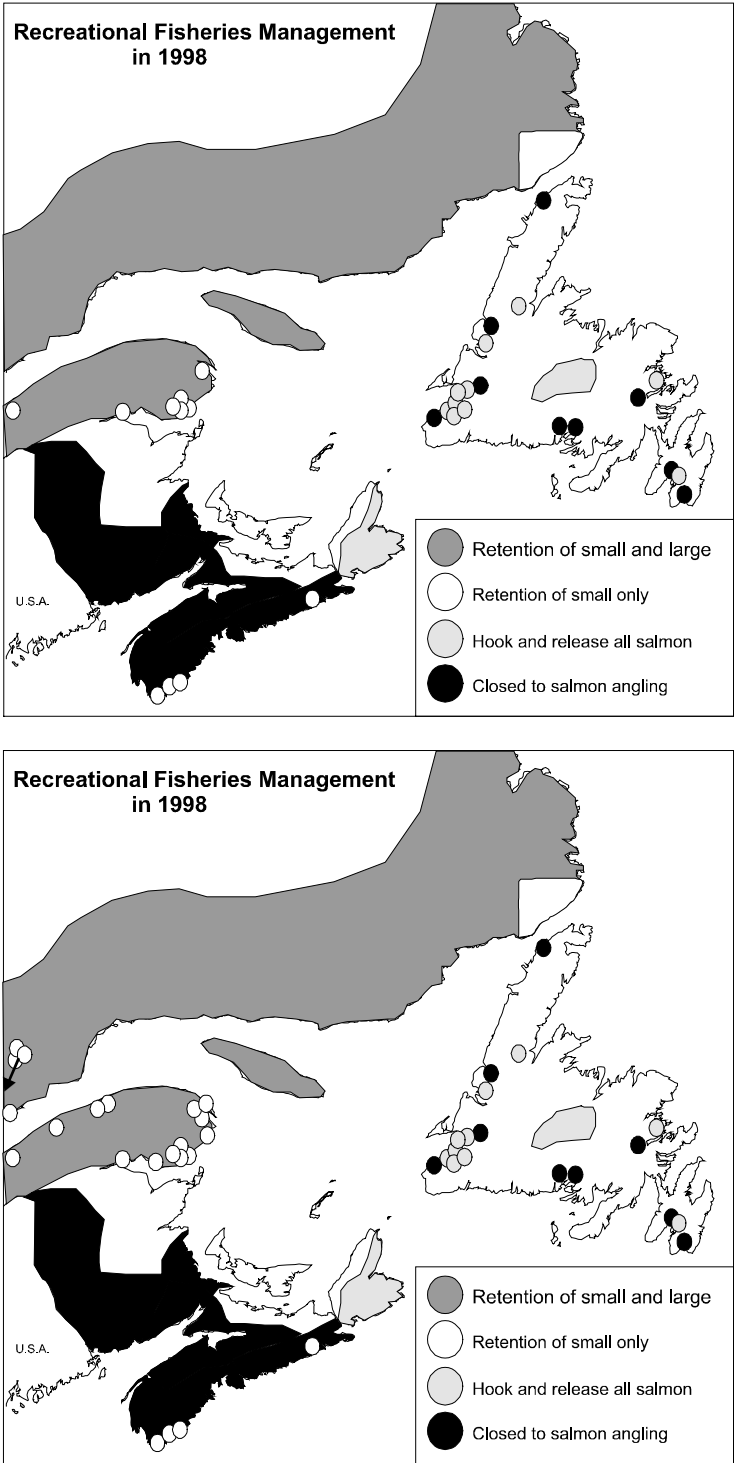

Figure 4.1.2.1. Harvest (t) of small salmon, large salmon, and combined in Canada, 1960 to 1998.

Figure 4.1.2.2. Harvest (number) of small salmon and large salmon and both sizes combined in the recreational fisheries in Canada, 1974 to 1998.

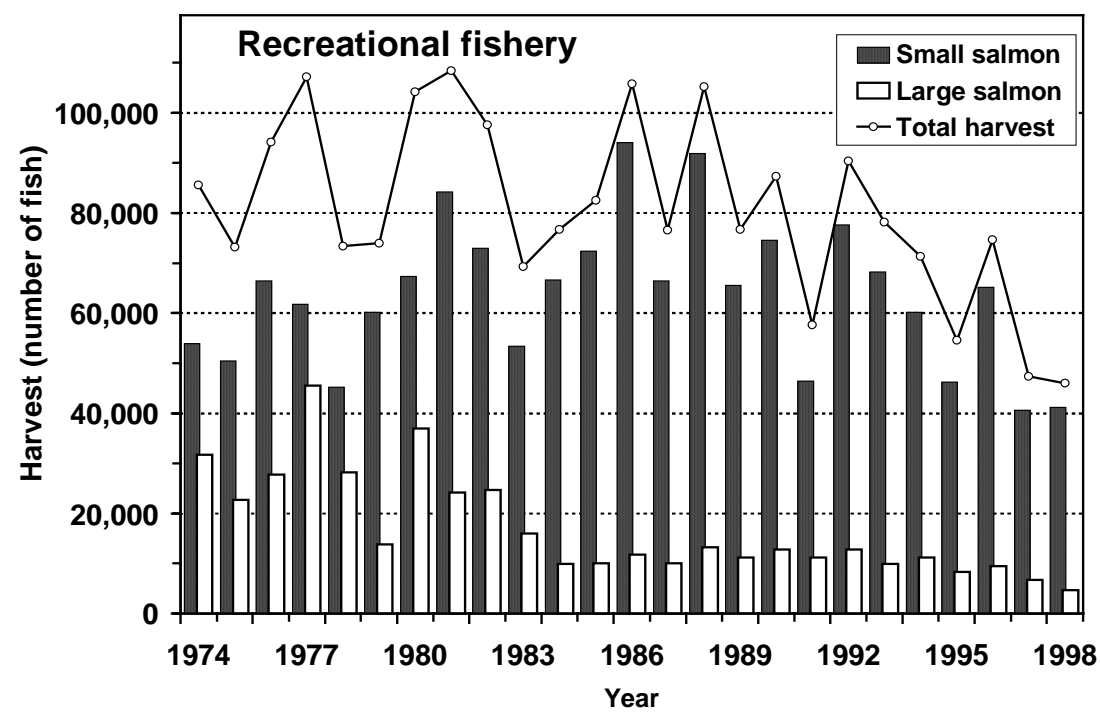

Figure 4.1.2.3. Angling catches (including kept and released fish) of small and large salmon by management area in 1998 (black square) expressed as a percentage of the average catches for the period 1984 to 1991. The vertical lines represent the minimum to maximum range. The 1984 to 1991 standard period was selected to represent the period of no commercial fisheries in SFAs 15 to 23 and Zones Q1 to Q6 and before the commercial salmon moratorium in Newfoundland SFAs 3 to 14A introduced in 1992.

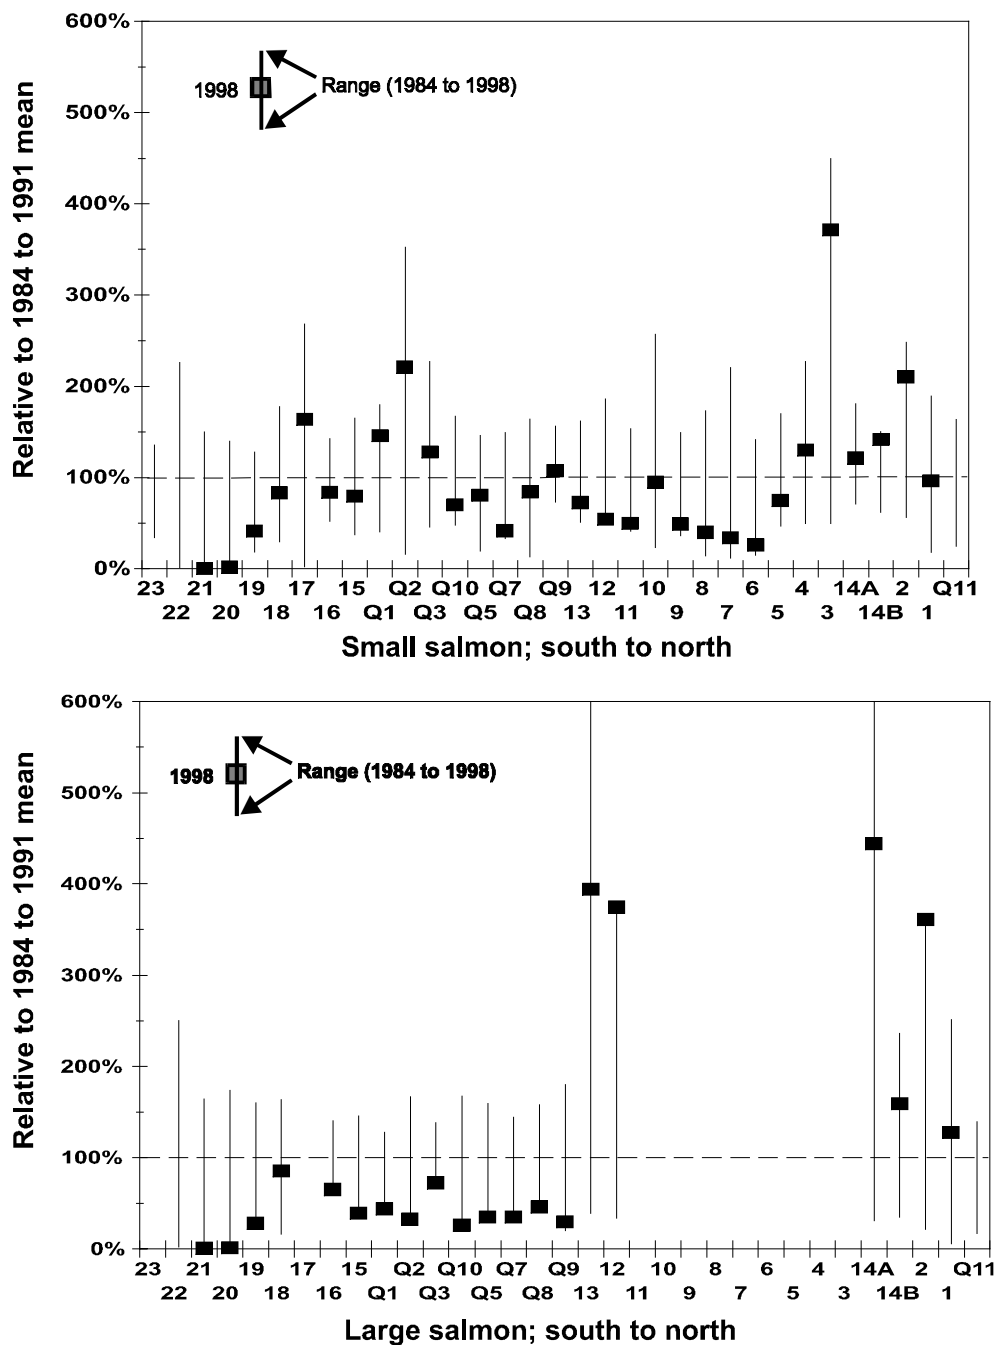

Figure 4.1.2.4. Harvest (t) of small salmon and large salmon and both size groups combined in the commercial fisheries of Canada, 1974 to 1998.

Figure 4.1.3.1. Origin (wild, hatchery, aquaculture) of Atlantic salmon returning to monitored rivers of eastern Canada in 1998. Only rivers in which more than one origin type were observed are indicated.

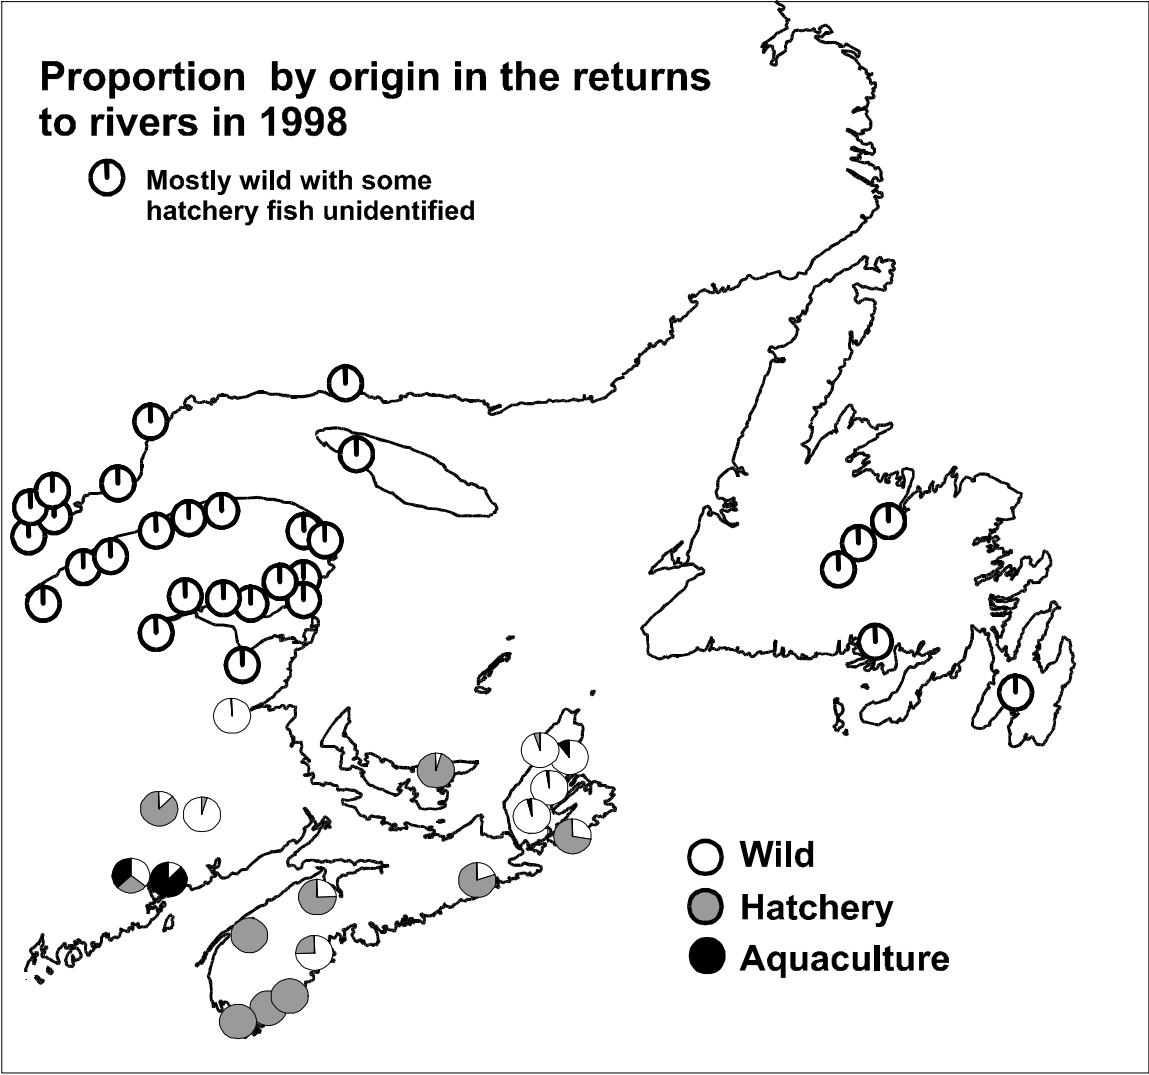

Figure 4.1.3.2. Location of Atlantic salmon marine grow-out sites in eastern North America (upper panel) and distribution of rivers with observed juvenile or adult aquaculture escaped Atlantic salmon (lower panel).

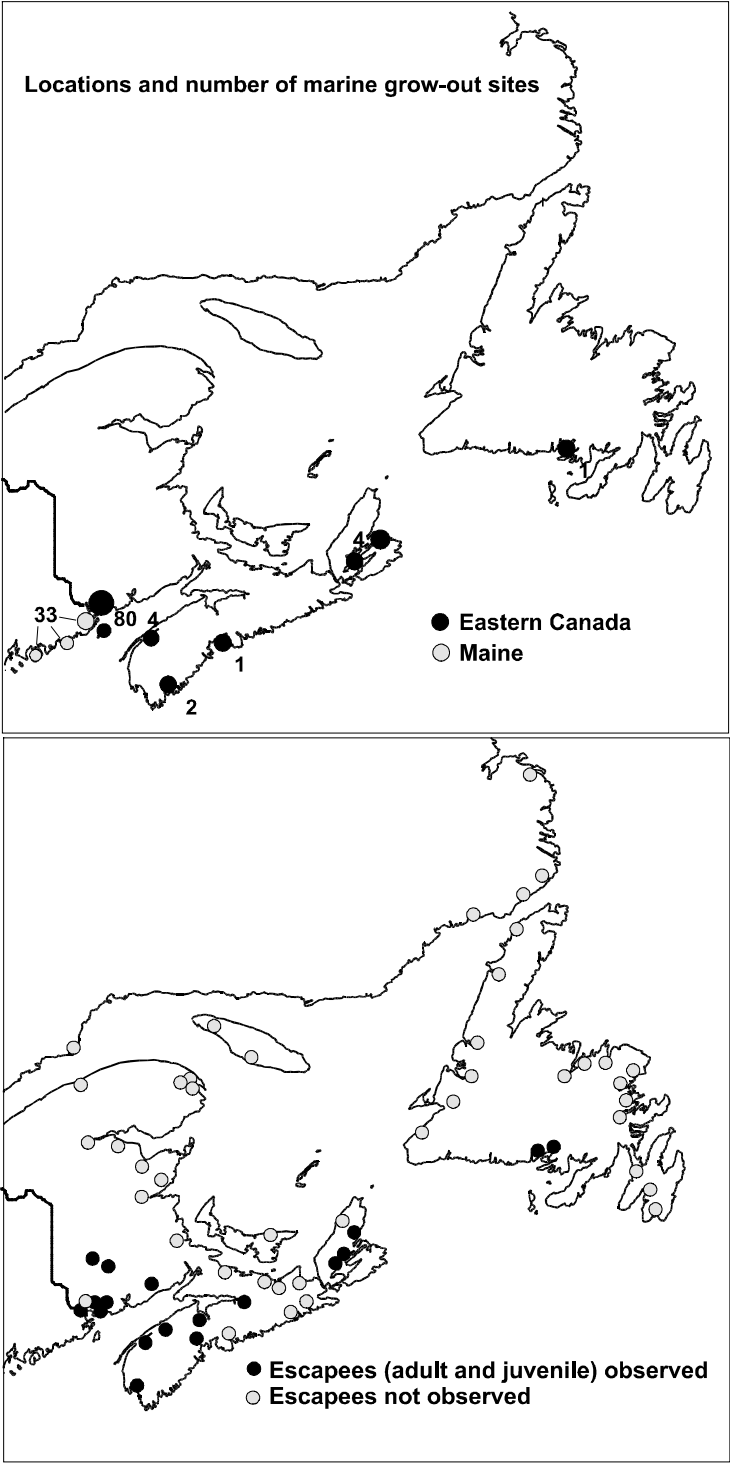

Figure 4.2.1.1. In-river returns of small salmon and large salmon for 51 monitored rivers of eastern Canada in 1998 relative to 1997.

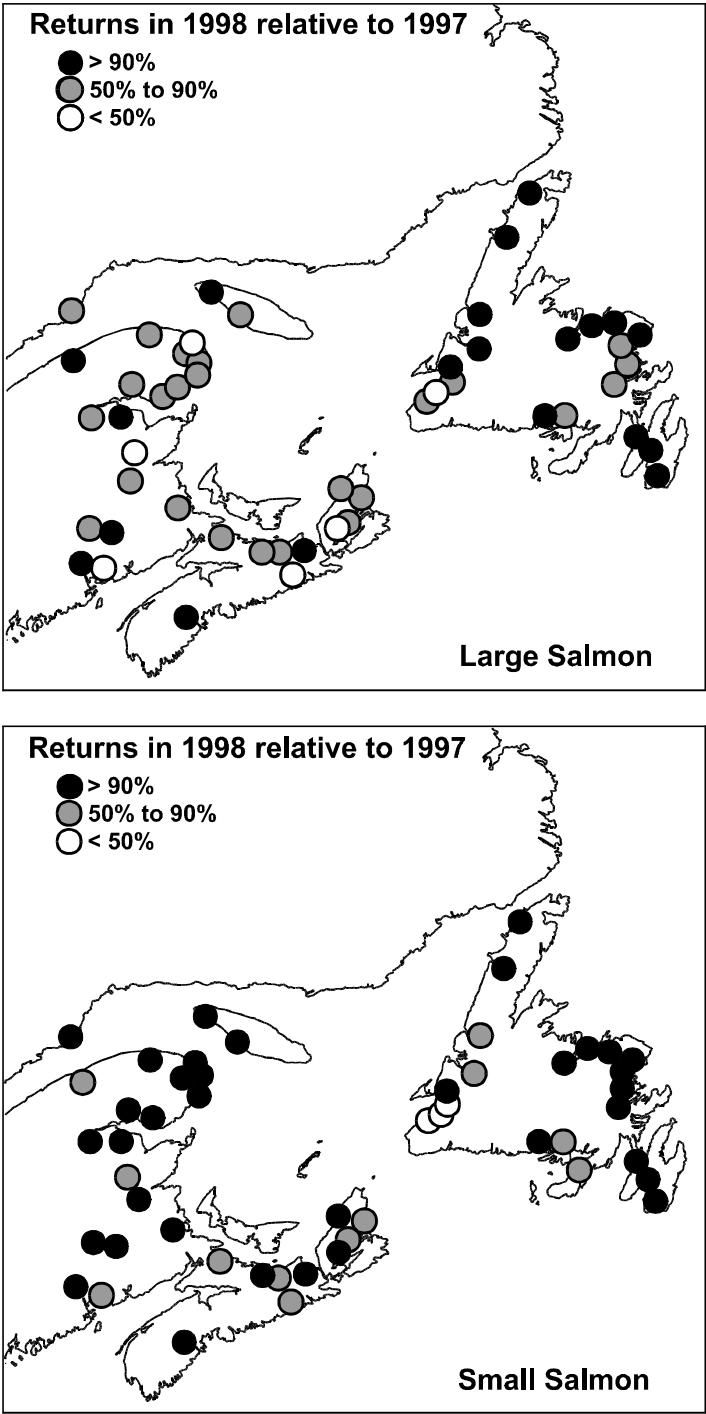

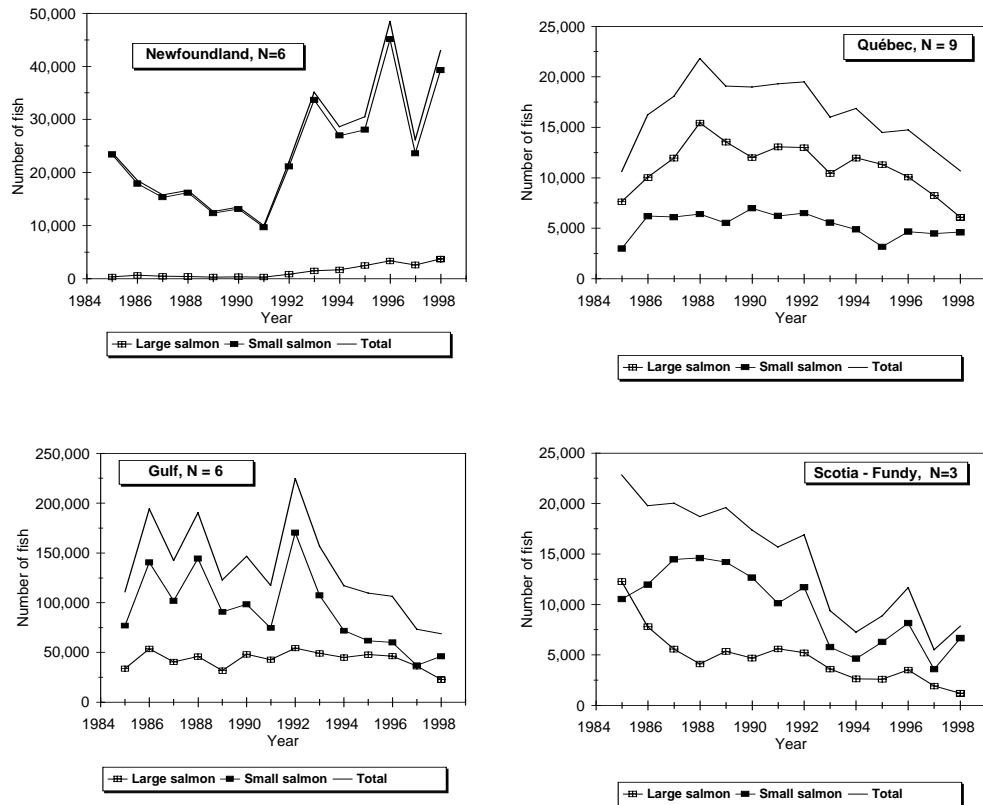

Figure 4.2.1.2. In-river returns of small salmon and large salmon for 24 monitored rivers in four geographic areas of eastern Canada from 1985 to 1998. The in-river returns do not account for removals in marine fisheries. Rivers by area are: Newfoundland (Exploits, Middle Brook, Terra Nova, Northeast Brook, Torrent, Western Arm Brook), Québec (Bonaventure, Cascapédia, St-Jean, York, Darmouth, Madeleine, Matane, de la Trinité, Bec-scie), Gulf (Restigouche, Miramichi, Philip, East Pictou, West Antigonish, Margaree), and Scotia-Fundy (Liscomb, LaHave, Saint John at Mactaquac).

5 ATLANTIC SALMON IN THE WEST GREENLAND COMMISSION AREA

5.1 Description of Fishery at West Greenland

5.1.1 Catch and effort in 1998

At its annual meeting in 1998 the West Greenland Commission of NASCO agreed that the catch at West Greenland should be restricted to that amount used for internal consumption in Greenland, which in the past has been estimated at 20 t. The Greenland authorities subsequently set this amount as total allowable catch.

The fishery was opened on August 16, and the season lasted to the end of the year. The total nominal catches amounted to 11 t (Table 5.1.1.1) of which a substantial part was taken late in the season. The geographical distribution of the nominal catches by Greenland vessels is given in Table 5.1.1.2 for the years 1977-98.

According to the regulations in force all catches, including landings to local markets, privately purchased salmon, and salmon caught by food fishermen, are reported on a daily basis to the Fishery Licence Office. In 1998 no landings to fish plants were permitted. Licences for the salmon fishery have been issued to fishermen fishing for the local markets, hotels, hospitals etc., while fishing for personal use was permitted without licence for residents of Greenland. In total, 321 licences were issued, however only 49 of these reported landings to local markets and private sales. Landings to local markets and salmon caught by food fishermen account for the largest part of the reported amount. Twenty-one persons were identified as food fishermen. Due to the new reporting system, the fishermen being personally responsible for reporting their catches, and due to the extremely scattered fishery a relatively large part of the total catches is considered to remain unreported. The unreported catches are estimated to be approximately 11 t in 1998.

5.1.2 Origin of catches at West Greenland

The Working Group examined the composition and origin of Atlantic salmon caught at West Greenland in 1998 based on discriminant analysis of characteristics from 532 samples from NAFO Div. 1D (August 17 to 21) and 8 samples from Div. 1E (August 12). Within the limited spatial and temporal scope of catch sampling, a randomised sampling design was used to obtain samples from salmon landed by fishing vessels in these areas during the local food fishery. The Working Group noted that samples were collected over a five-day period and only at two sites, one in NAFO Div. 1D and the other in 1E. While the Working Group recognized the difficulties with sampling a fishery with very small catches potentially well spread out in time and space, it was felt that the spatial and temporal distribution of the samples were not adequate to well define the characteristics of salmon in the local consumption fishery. Nevertheless, the samples are valid for defining biological characteristics and proportions of North American/European origin within the time and geographical scale from which they were collected.

Since 1969, discriminant analysis of scale characters from scales taken from salmon caught in the commercial fishery has been used to determine the proportions of the two continental stock groups in this fishery. The technique has proven to be a reliable method for discriminating and identifying salmon caught in this fishery (Lear and Sandeman 1980; Reddin 1986; Reddin *et al.* 1988; Reddin *et al.* 1990). Beginning in 1986, a combined genotypic/phenotypic approach was used whereby a subset of the samples obtained from the Greenland fishery was also sampled for liver and muscle tissue, from which continent of origin was determined using genetic protein polymorphisms (Reddin *et al.* 1990). The scale characters from this subset were used as a database for discriminant analysis to determine the proportions of North American and European salmon in all of the samples from this fishery. In 1995, the genetic technique was changed from protein polymorphisms to nuclear and mitochondrial DNA, which have been shown to provide a more reliable identification to continent of origin. This combined genotypic/phenotypic approach was used again in 1998 to develop a database to determine the proportions of North American and European salmon at Greenland.

Samples of muscle tissue were taken from salmon landed in Nuuk, Greenland during the 1998 sampling programme at Greenland. Samples were identified to continental origin based on microsatellites. In total, there were 121 North American and 35 European samples collected with nuclear DNA (microsatellites) and scale character information. Because of the low number of European samples the discriminant analysis was done by bootstrap. Samples of 35 North American and 35 European were randomly selected from the overall database and were used to classify the 540 samples of unknown origin from the fishery samples. This procedure was repeated 1,000 times outputting the probabilities of group membership which were then averaged to provide the final classifications to North American or European groups. The results of a cross-validation procedure indicated misclassification rates of 16% and error rates of $\pm 1\%$. This is an acceptable level of error. The method of Pella and Robertson (1979) was used to correct for misclassifications and gave an overall percent North American origin of 79% and European origin of 21 % (Table 5.1.2.1). Continent of origin was also determined in the samples collected for DNA analysis. In these samples, the overall percent North American was 78%, a difference of 1 % from the samples determined by scale analysis.

Applying the results of the above analysis to the reported catch indicated that 8.6 t (3,100 salmon) of North American origin and 2.6 t (900 salmon) of European origin were landed in West Greenland in 1998. This indicates that the numbers of North American salmon landed at West Greenland is reduced by 9,800 (75%) from 1997, while the numbers of European salmon caught is reduced by 7,400 (89 %). The data for 1982 to 1998 (no data for 1993-94) are summarised in Table 5.1.2.2, Figure 5.1.2.1.

The results of DNA analysis have also become available for the years 1995-97. These samples allow for the recalculation of the proportion of North American and European salmon using within year samples of known origin. This is a previous recommendation of the Working Group as it is felt that this type of analysis will allow for better classifications with lower error rates. A similar procedure was followed to that described above for 1998 with a bootstrap procedure used to classify individual salmon. The results of this analysis and comparison of the results from the scale technique gave the following:

Year	North American %		European %	
	DNA	Scales	DNA	Scales
1998	78	79	22	21
1997	72	77	28	23
1996	67	73	33	27
1995	89	68	11	32

This comparison of the results from DNA and scales demonstrates the good correspondence between the two techniques. While the two series of North American and European are not directly comparable because the scale samples have much higher sample sizes in some years, the correspondence is best when samples are most similar, i.e. 1996-98. Scale determination of continent of origin in 1995 came from over 2,000 samples while the DNA came from only 122 collected over a much shorter time scale. Also, it indicates that the proportion of North American salmon in the local food fishery in 1998 and previously in the commercial fishery, 1995-97, has been quite high. Because the biological characteristics from the salmon in the above analysis were not immediately available, the Working Group recommended that the new proportions not be considered until next year.

5.1.3 Biological characteristics of the catches

Biological characteristics (length, weight, and age) were recorded from 540 samples of catches from NAFO Div. 1C and 1E in 1998 using the results of discriminant analysis to divide samples into North American and European components. The data for 1998 are compared with those for previous years in Tables 5.1.3.1 to 5.1.3.3.

The downward trend in mean length of both European and North American 1SW salmon since 1969 changed in 1996, as mean lengths increased. From 1996 to 1998 the mean lengths decreased only slightly, being almost equal to the mean lengths observed since 1989 (Table 5.1.3.1).

Distribution of the catch by river age in 1968-98 as determined from scale samples is shown in Table 5.1.3.2. The proportion of the European origin salmon that were river-age three fish increased through 1995-97 to 37.8% in 1997, which is much greater than the overall mean of 17.4%. In 1998 a low proportion of 7.6% of river-age three was observed, the lowest on record. During the last two years the proportions of river-age two of North American origin salmon have declined appreciably from the 1968-95 mean of 36.5% to 20.4%, however with a slight increase from 1997 to 1998.

The sea-age composition of the samples collected from the West Greenland fishery showed a slight decrease in proportion in the North American component of 1SW fish from 1997 (98.0%) to 1998 (96.8%) (Table 5.1.3.3), these values being among the highest in the time series. The proportion of 1SW salmon in the European component in 1998 remained at the high level observed in 1997 (changed from 99.7% to 99.4%). Both components exhibit the highest recorded proportion of 1SW fish since 1969.

5.2 Status of the stocks in the West Greenland area

The salmon caught in the West Greenland fishery are non-maturing 1SW salmon or older, nearly all of which would return to homewaters in Europe or North America as MSW fish if they survived. While non-maturing 1SW salmon make up more than 90% of the catch there are also 2SW salmon and repeat spawners including salmon that had originally spawned for the first time after 1-sea-winter. The most abundant European stocks in West Greenland are thought to originate from the UK and Ireland although low numbers may originate from northern European rivers. For North

American MSW salmon, the most abundant stocks in West Greenland are thought to originate in the southern area of the range.

For the Northeast Commission area, a run-reconstruction model was used to update the estimates of pre-fishery abundance of non-maturing 1SW salmon (Table 3.6.2.4). The main contributor to the abundance of the European component of the West Greenland stock complex is non-maturing 1SW salmon from the southern areas of Europe. These stocks appear to have been more volatile, with large fluctuations occurring in the first half of the time series. Over the past 12 years, however, there has been a steady decline in non-maturing 1SW salmon from Southern European stocks.

Conservation limits and the time series of spawners have been provided for 16 rivers in the NEAC area. Only six of the 16 rivers had egg depositions above their conservation limits in the later years. There were no significant trends noted in the spawner attainment over the last ten years for all stocks combined, but a significant trend towards lower egg deposition was noted over the most recent 5-year period (Section 3.4). No category of rivers with an increasing trend could be identified, but 1998 represented an improvement over 1997 for 12 out of the 16 rivers.

In most parts of the NEAC area, marine survival was lower than the previous 5-year mean. However, analysis showed no significant trends in marine survival for the last 5- and 10-year periods. Marine survival rates for six hatchery stocks showed a downward trend in survival to homewaters for 1SW and 2SW salmon for the past 10-year period, but no significant trend was observed for the past 5-year period.

In general, there has been no significant change in smolt production in the Northeast Atlantic. Returns of salmon to most European rivers showed a significant downward trend for the last five years but no trend for the last 10 years.

For the North American Commission area, the North American run-reconstruction model was used to update the estimates of pre-fishery abundance of non-maturing and maturing 1SW salmon from 1971-97. The 1997 estimate of pre-fishery abundance of non-maturing 1SW salmon was the lowest on record. Pre-fishery abundance in 1997 has declined by 23% from the 1996 value (Section 4.2.3, Figure 4.2.3.1). In addition to the steady decline in total recruits (both maturing and non-maturing 1SW salmon) over the last ten years, maturing 1SW salmon (grilse) have become an increasingly large percentage of the North American stock complex. This percentage has risen from about 45% at the beginning of the 1970s, to around 70% in 1992-95 to almost 80% in 1997-98.

The estimate of the total number of 2SW salmon returning to Newfoundland rivers and coastal waters of other areas of North America in 1998 is 19% lower than the estimate for 1997 and lower than the average of the previous years (1971-96). It is the lowest observed in the past 10 years and second lowest in the 28 year time series, 1971-98 (Table 4.2.2.2). The estimates of returns are quite variable over the time series with no trends indicated. Returns have declined from a peak of 226,000 in 1980.

In most regions apart from Newfoundland, the returns of 2SW fish in 1998 are near the lower end of the twenty-seven year time series. However, returns of 2SW salmon to Labrador in 1995 and 1996 were the best in the time series. The estimated returns decreased again in 1997. No estimate is given for 1998 from this area, there being no commercial fishery, which was the basis for the return and spawner model for Labrador.

The majority of the USA returns were recorded in the rivers of Maine. The estimated 2SW returns and spawners to USA rivers in 1998 was only 5% below the 1997 estimate, but was 18% and 41% below the previous 5-year and 10-year averages, respectively. Returns to most USA rivers are hatchery-dependent. Spawning escapements remained at low levels (5%) compared to conservation requirements.

Egg depositions exceeded or equalled the specific conservation requirements in 21 of the 71 rivers (30%) that were assessed in Canada and were less than 50% of requirements in 24 other rivers (34%). Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where eight of the 12 rivers assessed (67%) had egg depositions that were less than 50% of conservation requirements (Figure 4.2.4.1).

North American salmon stocks remain at low levels relative in the 1970s. The 1SW non-maturing component continues to be depressed with river returns and total production amongst the lowest recorded. In addition, returns in 1998 of maturing 1SW salmon (grilse) to North American rivers were among the lowest in the 28-year time series. This being the case, improvement in 2SW salmon returns and spawners is unlikely in 1999. Only Newfoundland achieved its spawning requirements for 2SW salmon in 1998, where 2SW salmon comprise only a small proportion of salmon production. The next highest was the Gulf of St. Lawrence, where 2SW salmon are a high proportion of production and very important in terms of their contribution to both North American and Greenland fisheries (Section 4.2.6).

Despite some improvements in the annual returns to some rivers, both in European and North American areas, the overall status of stocks contributing to the West Greenland fishery remains poor, and as a result, the status of stocks within the West Greenland area is thought to be low compared to earlier (historical) levels.

5.3 Evaluation of the Effects on European and North American Stocks of the West Greenland Management Measures since 1993

There have been two significant changes in the management regime at West Greenland since 1993. First, NASCO adopted a new management model based upon ICES' assessment of the PFA of non-maturing 1SW North American salmon and the spawner escapement requirements for these stocks. This resulted in a substantial reduction in the TAC agreed to by NASCO from 840 t in 1991 to 258 t in 1993, and further reductions in subsequent years. The second change in management was the suspension of fishing in 1993 and 1994 following the agreement of compensation payments by the North Atlantic Salmon Fund. Due to the closure of the fishery in the two years no sampling could be carried out in Greenland, and no information on the biological characteristics was thus obtained. To calculate a possible TAC for those years according to the agreed quota allocation model (Anon. 1993) biological parameters from sampling in 1992 were used (Table 5.3.1). The mean weights, proportions of NA fish, and age correction factors in the Table are those used for projection purposes by the Working Group.

The numbers of fish spared by the closure are shown in Table 5.3.2. The potential catches in the two years of 89 and 137t, respectively, correspond to the TACs calculated in accordance with the quota allocation computation model that was agreed by NASCO at its annual meeting in 1993. For the successive years nominal catch figures are used. The Table shows the number of salmon returning to home waters provided no fishing of the given magnitude took place in Greenland. The biological parameters given in the Table represent the annual sampling data.

The mean number for 1993-98 of potentially returning fish per ton caught at Greenland is calculated to 176 and 131 salmon, respectively.

In the years 1972-92 exploitation rates in Greenland of the North American component of the salmon stock fluctuated between 10 and 45% around an average of 30% (Figure 5.3.1). The management measures in force since 1993 resulted in an average exploitation rate of this component of 13%, about one-third of its previous level, for the period 1995-97, after reopening of the fishery in 1995.

5.4 Changes to the 'Model' Used to Provide Catch Advice and Impacts of Changes on the Calculated Quota

5.4.1 Changes from the 1998 assessment

The models used to predict pre-fishery abundance of the North American non-maturing stock complex and subsequent quota levels for West Greenland were unchanged from the 1998 assessment. The same independent variables used previously were found to provide an improved fit over last year's model. However, some of the input data streams were modified to reflect new information available to the Working Group. These included: improvement of the catch reporting system in the Province of Newfoundland and Labrador by inclusion of catch statistics from Aboriginal fisheries in northern Labrador; and another year of data was added to all data series. Changes from ICES 1998/ACFM:15 in the data used to estimate pre-fisheries abundance resulted in only a very small change in the pre-fishery abundance estimates for most years or no change at all. In addition to the changes discussed above, we also note that the 1998 catch advice of 0 t would not have been different if the 1998 assessment had been done with the revised input data from this year. Although not completely appropriate, an assessment of what the forecast value would have been is 108,700 (Table 5.6.1.1).

5.4.2 Impact of changes on the catch advice

Modifications and improvement to the data streams used to predict pre-fishery abundance would impact the quota in various ways. Modifications to the data that increase the estimated pre-fishery abundance will tend to increase the quota by potentially providing more fish to the surplus portion of the populations. The opposite is also true. Since the updates made in the database resulted in a fit that was only slightly different than in the 1997 assessment, we can conclude no change would have occurred to the 1998 forecast.

5.5 Age-Specific Stock Conservation Limits for All Stocks in the West Greenland Commission Area

Sampling of the fishery at West Greenland (Table 5.1.3.3) since 1985 has shown that both European and North American stocks harvested there are primarily (greater than 90%) 1SW non-maturing salmon that would mature as either

2 or 3 SW salmon, if surviving to spawn. Usually less than 1% of the harvest are salmon which have previously spawned and a few percent are 2 SW salmon which would mature as 3SW or older salmon, if surviving to spawn. In 1998, 96.8% of the sampled catch was North American origin and 99.4% of the sampled catch was 1SW salmon of European origin. For this reason, conservation limits defined previously for North American stocks have been limited to this cohort (2SW salmon on their return to homewaters) that may have been at Greenland as 1SW non-maturing fish. These numbers have been documented previously by the Working Group and are revised this year in Section 4.4. From Table 4.4.1, the 2SW spawning requirements of salmon stocks from North America which may be present in the West Greenland Commission Area total 183,852 fish, with 154,653 and 29,199 required in Canadian and USA rivers, respectively.

The Working Group revised their estimates of provisional conservation limits for MSW salmon in Europe based on the methods developed in 1998 (ICES 1998/ACFM:15) and the improvements outlined in Section 3.7.1 (Table 3.7.2.1). The conservation limits were split into 1SW and MSW components on the basis of the average age composition of catches in the past ten years. The stocks have also been partitioned into northern and southern groups, and tagging information and biological sampling indicates that the majority of the European salmon caught at West Greenland originate from the southern group. The provisional conservation limit for southern European MSW stocks is approximately 470,000 fish (Table 3.7.1.1).

5.6 Catch Options with Assessment of Risks Relative to the Objective of Achieving Conservation Limits

5.6.1 Overview of provision of catch advice

The Working Group was asked to advise on catch levels based upon maintaining adequate spawning escapements sufficient to achieve conservation limits. Although advances have been made in our understanding of the population dynamics of Atlantic salmon and the exploitation occurring in the fisheries, the concerns about the implications of applying TACs to mixed stock fisheries are still relevant. In principle, adjustments in catches in mixed-stock fisheries provided by means of an annually adjusted TAC would reduce mean mortality on the contributing populations. However, benefits that might result for particular stocks would be difficult to demonstrate, in the same way that damage to individual stocks are difficult to identify.

In 1993, the Working Group considered how the predictive measures of abundance could be used to give annual catch advice (ICES 1993/Assess:10; Sections 5.3 and 5.4). The aim of management would be to limit catches to a level that would facilitate achieving overall spawning escapement equivalent to the sum of spawning requirements in individual North American and European rivers (when the latter have been defined). In order to achieve the desired level of exploitation for a given level of predicted abundance, a TAC could be fixed or some form of effort adjustment introduced.

The advice for any given year is dependent on obtaining a reliable predictor of the abundance of non-maturing 1SW North American stocks prior to the start of the fishery in Greenland. Gill net fisheries in Greenland and Labrador harvest one-sea-winter (1SW) salmon about one year before they mature and return to spawn in North American rivers. This component is also harvested on their return as 2SW salmon in commercial fisheries in Québec, angling and native fisheries throughout eastern Canada and angling fisheries in the northeastern USA. The fishery in Greenland harvests salmon which would not mature until the following year while the fishery in Labrador (closed in 1998) harvests a mix from the non-maturing component as well as maturing 1SW and MSW salmon. The commercial fishery in Québec harvests maturing 1SW and MSW salmon.

The Working Group has advocated models based on thermal habitat in the northwest Atlantic to forecast pre-fishery abundance in order to provide catch advice for the West Greenland fishery. While the approach has been consistent since 1993, the models themselves have varied slightly over the years. The changes have been made to these models in attempts to improve the prediction and add more biological reality. The models of previous years included using the following predictor variables: 1993 - thermal habitat in March; 1994 - thermal habitat in March; 1995 - thermal habitat in January, February, and March; and 1996-97 - thermal habitat in February and lagged spawners from the Labrador, Newfoundland, Québec, and Scotia-Fundy regions of Canada.

North American run-reconstruction model

The Working Group has used the North American run-reconstruction model to estimate pre-fishery abundance of 1SW non-maturing and maturing 2SW fish adjusted by natural mortality to the time prior to the West Greenland fishery (See Section 4.2.3). Region-specific estimates of 2SW returns are listed in Table 4.2.2.2. Estimates of 2SW returns prior to 1998 in Labrador are derived from estimated 2SW catches in the fishery using a range of assumptions regarding exploitation rates and origin of the catch. With the closure of the Labrador fishery, 1998 returns were estimated as a proportion of the total for other areas based on historical data.

Update of thermal habitat

The Working Group has been using the relationship between marine habitat, 2SW spawners and pre-fishery abundance to forecast pre-fishery abundance (ICES 1993/Assess:10; 1994/Assess:16; 1995/Assess:14; 1996/Assess:11, 1997/Assess:10; and 1998/ACFM:15). Marine habitat is measured as a relative index of the area suitable for salmon at sea, termed thermal habitat, and was derived from sea surface temperature (SST) data obtained from the National Meteorological Center of the National Ocean & Atmospheric Administration and previously published catch rates for salmon from research vessels fishing in the northwest Atlantic (Reddin *et al.* 1993 and ICES 1995/Assess:14). The SST data were determined by optimally interpolating SSTs from ships of opportunity, earth observation satellites (AVHRR), and sea ice cover data. The area used to determine available salmon habitat encompassed the northwest Atlantic north of 41°N latitude and west of 29°W longitude and includes the Davis Strait, Labrador Sea, Irminger Sea, and the Grand Bank of Newfoundland.

Thermal habitat has been updated to include 1998 data. Two periods of decline in the available habitat are identified (1980 to 1984 and 1988 to 1995) in the February index (Table 5.6.1.1 and Figure 5.6.1.1). Available habitat for February was reduced in 1999 below the 1998 level from 1849 to 1741, a decline of approximately 6%. The 1999 February value is still well above the long-term mean.

5.6.2 Forecast model for pre-fishery abundance of North America 2SW salmon

The 1999 forecast of pre-fishery abundance was based on regression analysis to predict the pre-fishery abundance of non-maturing 1SW fish prior to the start of the Greenland fishery. This makes the fourth consecutive year the same model has been used in the forecasting procedure. The basis for the model is two predictor variables: thermal habitat for February (term H2) and lagged spawners (sum of lagged spawners from Labrador, Newfoundland, Scotia-Fundy and Quebec, term SLNQ) (ICES 1996/Assess:11). This was justified on the basis of studies showing that salmon stocks over wide geographic areas tend to have synchronous survival rates and that the winter period may be the critical stage for post-smolt survival and maturation (Scarnecchia 1989; Reddin and Shearer 1987; Friedland *et al.* 1993; Friedland *et al.* 1998). Consequently, the model used in 1997 was updated to reflect the inclusion of the additional value and the refinement of other parameters to the time series of pre-fishery abundance estimates and then the 1999 pre-fishery abundance was forecasted.

The linear fit to the 1999 model of pre-fishery abundance versus February thermal habitat and lagged spawners (SLNQ) produced a significant relationship between observed and predicted values ($F_{2,17} = 37.4$) and all model parameters were significant at less than the 5% level (Table 5.6.2.1). Individually, the two predictor variables used are also significantly related to pre-fishery abundance (Figure 5.6.2.1).

The contribution of the two variables to the model fit has changed compared to what was previously the case, where SLNQ spawners contributed much less than February habitat. In the current analysis, February habitat accounted for 54% of the total sum of squares by itself but with SLNQ spawners included, the contribution of February habitat was only 15% of the overall variability while the contribution of SLNQ spawners was 28% (Table 5.6.2.1). The jackknife and simulated predicted values for pre-fishery abundance for 1978-99 are shown in Table 5.6.1.1 and Figure 5.6.2.2. The predicted values are shown to fit the observed data quite well except during the period of low abundance in 1978 and in the late 1980s and 90s when abundance was low. The high correlation between the observed and jackknife predictions ($r = +0.859$) can be seen in Figure 5.6.2.3A. The residual pattern for the model shows a positive relationship with observed values ($r = +0.430$) and there are low positive residuals at the end of the time series (Figure 5.6.2.3B). The forecasted estimate by simulation of pre-fishery abundance for 1999 using the February thermal habitat and lagged spawner model is about 79,500 at the 50% probability level (Table 5.6.1.1). Using the current model to estimate the 1998 pre-fishery abundance yields a value of 108,890, which is similar to the previously reported value of 113,899. It should be noted that deterministic and simulated forecast values will show differences due to the method of calculation.

The model continues to be influenced primarily by the spawning stock level in the predictive relationship for pre-fishery abundance (Table 5.6.2.1). Thus, the prediction of pre-fishery abundance would be moderated during periods of high levels of habitat and low levels of spawning stock. The alternate case would be an increase in predicted pre-fishery abundance when spawning stocks were high and thermal habitat was low. The former has occurred with the predicted values for 1998 and 1999, as thermal habitat has increased considerably, the predicted pre-fishery abundance in recent years is low due to the large decline in spawners producing them (Figure 5.6.1.1). Two-sea-winter spawners contributing to returns will not improve until the year 2000.

Stochastic Analyses

Although the exact error bounds for the estimates of NN1(i) are unknown, minimum and maximum values of component catch and return estimates have been estimated. Simulation methods, implemented in the software package SAS (SAS

Institute, 1996), were used to generate the probability density function of NN1(i). This was done as a six-step procedure as follows:

1. Annual values (1978–97) of pre-fishery abundance (NN1) were generated assuming a uniform distribution of the minimum to maximum values of input parameters NC1, NC2, and NR2.
2. The parameter values of the regression model of pre-fishery abundance on the February thermal habitat (H2) variable and the lagged spawners (SLNQ) variable were estimated from the data set generated in step 1.
3. A single pre-fishery forecast value for 1988 was obtained by drawing at random from a normal distribution defined by the mean forecast value and the mean square error of the estimate (for a single prediction) from the regression statistics. The normal distribution was used because the error structure of the regression is assumed to be normal.
4. Step 3 was repeated 1,000 times to generate a vector of forecast values from an individual regression fit.
5. Steps 1 to 4 were repeated 1,000 times to generate 1,000,000 predictions (1,000 times 1,000) of pre-fishery abundance. This resampling incorporates the uncertainty of the input parameters (step 1) and the unexplained variance in pre-fishery abundance from the regression (step 4).
6. The probability profile of these stochastic forecasts (in 5% intervals) of the pre-fishery abundance forecast was generated from the vector of pre-fishery abundance forecast values obtained in step 5 (Table 5.6.2.2).

These estimates can be used to quantify the probability that the actual stock is above the relative probabilities of attaining spawning requirements for the stock under different allocation schemes. Managers may also use this information to determine the relative risks borne by the stock (i.e., not meeting spawning requirements) versus the fishery (e.g., reduced short-term catches).

5.6.3 Development of catch options for 1999

Development of catch advice

Atlantic salmon are managed on the basis of ensuring adequate numbers of spawners in individual rivers. A composite spawning requirement for the North American 2SW stock complex was developed by summing the spawning requirements of Salmon Fishing Areas in Canada and river basins within the USA. Details on the methodology to estimate and update the spawning requirements are provided in (ICES 1996/Assess:11) and in Section 4.4 of this report. With these data, it is possible to compute an allowable harvest. This procedure is unchanged from the previous assessment and is shown in Appendix 7. Previously, NASCO considered all salmon above the conservation requirement as being available for harvest.

Catch advice for 1998

The fishery allocation for West Greenland is for 1SW fisheries in 1999, whereas the allocation for North America can be harvested in fisheries on 1SW salmon in 1999 and/or in fisheries on 2SW salmon in 2000. To achieve spawning requirements, a pool of fish must be set aside prior to fishery allocation in order to meet spawning requirements and allow for natural mortality in the intervening months between the fishery and return to river. In last year's report, a spawning requirement of 183,852 fish was reported for all North American rivers (ICES 1998/ACFM:15). Thus, 205,230 pre-fishery abundance fish must be reserved ($183,852/\exp(-0.01 \times 11)$) to ensure achievement of the requirement after natural mortality.

By using the probability density function of the pre-fishery abundance, the probability of the expected stock abundance being greater or lower than the value selected can be estimated. This probability level also provides a measure of the probability of reaching conservation requirements assuming fishery allocations are taken without error. The mean estimate of the forecast represents a reference point at which there is a 50% chance that the true abundance is lower than required to achieve the conservation requirement. Likewise, the forecast value at the 25th percentile, or the value with a 25% chance that the abundance is lower and the forecast value at 75th percentile, or the value with a 75% chance that the abundance is lower, characterise a range of decision with lower and higher risks, respectively.

Quota computation for the 1999 fishery requires an estimate of pre-fishery abundance [NN1], stock composition by continent [PropNA], mean weights of North American and European 1SW salmon [WT1SWNA and WT1SWE, respectively], and a correction factor for the expected sea-age composition of the total landings [ACF]. Exponential smoothing model forecasts utilising data collected during the 1997 fishery and using interpolated values for 1993 and 1994, with approximate 50% confidence limits, are summarised below.

<u>Parameter</u>	<u>Forecast</u>	<u>Minus 1SE</u>	<u>Plus 1SE</u>
PropNA	0.584	0.503	0.667
WT1SWNA	2.62	2.47	2.78
WT1SWE	2.74	2.56	2.92
ACF	1.118	1.018	1.21

The Working Group recommends that as these parameters have changed in the past, they should be updated with new data from sampling programs to ensure the greatest possible accuracy in the quota calculation. However, the absence of an adequate sample from the 1998 fishery precludes a new analysis.

Greenland quota levels for H2-SLNQ forecast of pre-fishery abundance were computed. The quota values based on this forecast between interquartile limits of the probability density function are presented in Table 5.6.3.1. For the point estimate level and the stochastic regression estimate using NN1, the quota options are all 0 t, regardless of the proportion allocated to West Greenland (FNA) or selection of a probability level between 25% and 75%.

The 50% risk level is intended to produce spawning escapements in North America that will meet the requirement level for all rivers combined 50% of the time. Even if this overall requirement is achieved, it is likely that some stocks will therefore fail to meet their individual spawner requirements while others will exceed requirement levels. This may result from random variation between years or from systematic differences in the patterns of exploitation on fish from different rivers or regions. In the latter case, adoption of a 50% risk approach may result in some stocks failing to meet requirement levels over an extended period if the full TAC is harvested. This could result in the long-term decline in those stocks.

The Working Group concludes that it is evident from both the indicators of stock status that the North American stock complex is in tenuous condition. If the forecast is accurate then pre-fishery abundance in 1999 will be lower than any other pre-fishery abundance value previously estimated despite nearly complete closures of mixed and single stock fisheries, a continuing trend of below requirement spawning escapements for 2SW salmon, and the low marine survival rates for some monitored stocks. The increasing advantage associated with each additional spawner in under-seeded river systems makes a strong case for a conservative management strategy.

5.6.4 Risk assessment of catch options

The provision of catch advice in a risk framework involves the incorporation of the uncertainty in all the factors used to develop the catch options. The ranges in the uncertainties of all the factors will result in assessments of differing levels of precision. The precision of the assessment has a potential effect on the risk approach used by managers. One approach considers the catch options relative to a 50% chance of the undesirable event occurring and ignores the uncertainty in the stock assessment. The reliability of the assessment has very different and profound consequences on the catch options for risk-averse compared to risk-prone approaches (Figure 5.6.4.1). In a theoretical example, two assessments provide the same point estimate (50% probability value) but the precisions are very different. Under a risk-prone management approach, the allowed catch would be greater for the imprecise assessment: at a 70% risk level, the advised catch under the precise assessment would be 500 t but the uncertain assessment would provide for a catch of 800 t (Figure 5.6.4.1). The risk-averse management approach would advise for lower catch options for the imprecise assessment: at a 20% risk level, the precise assessment would provide a catch option of about 400 t but for the imprecise assessment, no catch is advised. Under precautionary management principles (Section 2.7), a risk-averse approach would be favoured for imprecise assessments.

The analysis of risk involves three steps: 1) describing the precision or imprecision of the assessment; 2) the definition of a management strategy; and 3) the evaluation of the probability of an event (either desirable or undesirable) resulting from the fishery action. The management of Atlantic salmon in the North American and Greenland Commission areas involves managing for a fixed escapement of salmon to rivers in North America. The conservation requirements to North America are considered to be a threshold reference point. All potential recruits in excess of the conservation requirement are considered to be available for harvest. The undesirable event to be assessed is that the spawning escapement to North America will be below the conservation limit.

A risk analysis of catch options for Atlantic salmon from North America incorporates all the uncertainty in the estimates of the probable returns:

1. the conservation requirement risk plot,
2. the uncertainty of the pre-fishery abundance forecast, and
3. the uncertainty in the biological parameters used to translate catches (weight) into numbers of North American origin salmon.

The risk analysis plots are calculated for consideration of the 1999 fishery in West Greenland.

Spawner requirement risk analysis

The derivation of the spawning requirement risk plot for North America was similar to the method presented in ICES 1997/Assess:10. Briefly, North America is divided into six stock areas which correspond to the areas used to estimate returns and spawning escapements (Table 4.4.1). The annual variability in the proportion female in each stock area was described in terms of a uniform distribution corresponding to values for each stock area. A total of 1,000 simulations were run for each spawning escapement level. The sex ratio varied independently in each stock for each simulation. The risk plots were expressed as the probability of meeting or exceeding the spawning requirements concurrently in all six stock areas. In addition, plots of the probability of meeting or exceeding lower proportions of the spawning requirements were derived as an indication of the magnitude of under-escapement which would be expected for different levels of escapement to North American rivers.

Under the assumption of equal production from all stock areas (i.e., recruitment in direct proportion to the spawner requirement) just over 200,000 fish should escape to North America as spawners to achieve the spawner requirement in all six stock areas at a 50% probability level. This value is higher than the point estimate for the North American stock complex (183,852 2SW salmon, Table 4.4.1) because it includes the annual variation in proportion female.

Pre-fishery forecast abundance uncertainty

Model fitting and the confidence intervals for the pre-fishery abundance of non-maturing North American origin salmon are described in Section 5.6.2. The required elements for the risk analysis are the distributions of pre-fishery abundance and their associated probabilities (Figure 5.6.4.2).

Uncertainty in the biological characteristics and predicted catches of North American origin salmon

The catch options table (Table 5.6.3.1) is calculated using the probability density function of the pre-fishery abundance forecasts and point estimates for the remaining parameters including: the spawner reserve for North America, proportion of the 1SW catch which would be of North American origin, weight of 1SW North American and European fish, and the age correction factor. The predicted stock characteristics for 1999 and their associated errors were the same as those of 1998 (Section 5.6.3). In the risk analysis, the biological characteristics were modelled assuming a normal distribution with a mean and standard error generated from the exponential smoothing function for the 1998 characteristics (Section 5.6.3). The only exception was for the age correction factor (ACF) for which the lower bound was trimmed to unity. The resultant distributions from 1,000 iterations appropriately represented the initial input parameters with the exception of the ACF distribution (Figure 5.6.4.3). An alternative to the normal error distribution for the ACF parameter was not explored at this meeting.

Using the biological characteristics and the catch options, the total returns to North America after the Greenland fishery were calculated by subtracting the catch of North American 1SW origin salmon from the pre-fishery abundance forecast and discounting for the 11 months of natural mortality between the time of the Greenland fishery and return to homewaters. An example of the distribution of harvest (numbers) of North American origin salmon for a quota of 100 t at West Greenland, which incorporated the uncertainty in the biological characteristics, is shown in the middle panel of Figure 5.6.4.2. The distribution of returns to North America after harvest at Greenland, which incorporates the uncertainty in the pre-fishery abundance forecast and the uncertainty in harvest numbers, is shown in the bottom panel of Figure 5.6.4.2.

Catch options and risk summary for 1999

The final step in the risk analysis of the catch options involves combining the cumulative risk plots from the conservation requirement calculation with the probability distribution of the returns to North America for different catch options. The sum of the products of the cumulative distribution of spawner requirements and the probability distribution of the corresponding returns to North America equals the probability of meeting the conservation requirements. The risk of not meeting the conservation requirement in at least one of the six stock areas is obtained by subtracting from unity the probability of meeting the requirements in all the areas. An analysis of the risk of the severity of the underescapement (for example, the risk of not attaining 50% of the conservation requirement in at least one of the six stock areas) was derived in exactly the same way by substituting the cumulative distribution for a different conservation requirement proportion.

The pre-fishery abundance of salmon in 1999 is expected to be low (Figure 5.6.4.2). There is a high risk (85% probability) that the returns of 2SW salmon to North America in 2000 will be below the conservation requirement in at least one of the six stock areas, even in the absence of any fisheries-induced mortality on this age group in Greenland in 1999 and North America in 2000 (Figure 5.6.4.4). There is a high probability (55% chance) that at least one of the six stock areas will be severely underescaped (by 50%). The risk profile is shallow over the range of catch options illustrated (0 to 1000 t) which reflects the degree of uncertainty in the expected abundance relative to the catch options considered.

The impact of the combined Greenland and North American fisheries must also be considered. The fisheries exploitation rates in North America in the last few years were estimated to be between 0.15 and 0.25 (Section 4.1.4). Assuming that fisheries management in North America in 2000 would be similar to recent years, then it would be expected that, at most, 15 to 25% of the 2SW returns to North America would be removed prior to spawning. Exploitation rates on 2SW salmon have declined in Canada as a result of the closure/reduction of the commercial fisheries and closure of many angling fisheries (Section 4.1). The impact of such a fishing scenario in North America on the salmon returning to homewaters in 2000, in the absence of any fishery at Greenland in 1999, results in a high risk (92%) of not meeting the conservation requirements in at least one of the six stock areas (Figure 5.6.4.4 lower panel). This assumes that salmon will return to each geographic area in proportion to the relative conservation requirements in each area and that the exploitation rates in each of the six stock areas are similar. Although this is not true (see Section 4.1.4, 4.2.2), it was the only scenario considered by the Working Group at this meeting. Under further reduced exploitation rates in North America, there is no less than an 85% chance that conservation requirements will not be met.

The cumulative consequences of fisheries at Greenland (1999) and in North America (2000) on the potential spawning escapements to North American stock areas increases the risk of severe underescapement (50% of conservation requirements) in North America. There is a 55% risk of severe underescapement with no fisheries and the risk rises to greater than 61% at a Greenland catch option of 50 t and exploitation rates between 0.15 and 0.25 in North America (Figure 5.6.4.4). Considering the uncertainty in the assessment of the abundance of North American salmon in West Greenland in 1999, precautionary approach principles in managing the both the Greenland and North American salmon fisheries are advised.

5.7 Critical examination of the Confidence Limits on the Output of, and Assumptions in, the ‘Model’ Used to Provide Catch Advice

5.7.1 Introduction

This is the second year that the Working Group considered this request. This is because there was neither a “workshop”, as proposed in the Terms of Reference adopted at the 1998 Statutory Meeting (C.Res. 1998/2:4: “Comment on the Report of the Workshop on Peer Review of ICES Salmon Model”) nor a report on which to comment. In the absence of same and in recognition of the weaknesses of the existing models the Working Group focused on several initiatives.

Brief description of the ‘model’

The Greenland pre-fishery abundance estimate (PFA) is generated as described in previous reports (ICES 1998/ACFM:15, section 5.5). First, the 2SW returns of salmon to specific regions in North America (Labrador, Newfoundland, Québec, Gulf of St. Lawrence, Scotia-Fundy and the USA) are estimated by various means (counting fences, catches, mark-recapture estimates, etc.), and the numbers for returns and catches are entered into the continental run reconstruction model for North America. This model looks backward in time, after all fisheries and spawning runs are complete, to provide a final estimate of what the prefishery abundances were in the preceding year, and what mortalities resulted from the various fisheries.

To forecast PFAs for the upcoming year, a second model is employed which incorporates terms for February sea surface temperatures (SSTs) in the ocean area where salmon are believed to be residing, and a “lagged spawner” estimate (derived from the run reconstruction model) as a surrogate for the number of smolts which would have previously migrated to sea and which should be contributing to the upcoming year’s fishery. Both of these variables have been shown to have a significant relationship with the PFAs, and it is these relationships that permit the working group to provide PFA forecasts.

Confidence limits

Currently, estimates of pre-fishery abundance forecast error in the model to forecast salmon in the Northwest Atlantic are based on a series of empirically derived confidence intervals developed for some, but not all of the variables included in the regression model. The Working Group considered an alternate estimation procedure that utilizes the error structure from the base regression model residuals to develop a bootstrap sample of forecasts. The resultant probability density function from the bootstrap sample was compared to the current assessment results. The bootstrap sample appeared to contain bias, a feature not uncommon for this class of models. The probability density distribution of the bootstrap sample was close to the one generated by both the current re-sampling procedure, and to the confidence interval resulting from the base regression itself. This convergence of techniques was noted by the Working Group; however, it was felt to be premature to apply the bootstrapping approach until this bias could be better understood and a correction procedure appropriate to the data could be developed. The Working Group encourages further work on the bootstrapping approach.

5.7.2 Impact of measurement errors on 1999 PFA forecast

The forecast of the North American PFA is based on a two variable linear model: the lagged spawners and the February habitat. Twenty years of data are available to fit the model (1978 to 1997) and a prediction is derived for 1999 based on the observations of the independent variables collected for that year. This linear regression can be treated under a Bayesian approach (Gelman *et al.* 1995). The posterior predictive distribution of the 1999 PFA forecast is a Student-t centered on the point estimates that would be obtained under classical least squares fitting. The posterior uncertainty of this prediction is shown in Figure 5.7.2.1. Negative values are excluded as *a priori* impossibilities.

Measurement errors can have disruptive effects on model fitting and on the uncertainty of the predictions. An analysis was conducted to assess the potential effect of measurement errors on the PFA and the lagged spawners, because both are derived from estimation procedures and are not readily observable. In contrast, the habitat variable was regarded as an actual measure without errors, because it is derived from a collection of "field" temperature measurements. Accounting for the measurement errors reflects that the information introduced in the PFA estimation procedure (the first twenty years of data plus the independent variables for 1999) are less informative than the point estimates of the variables would tend to suggest. As a consequence, the uncertainty of the 1999 prediction should increase.

Accounting for measurement errors under the Bayesian framework is equivalent to generating data sets under a probabilistic description of their error structure and averaging the resulting posterior distributions of interest (the 1999 PFA prediction) over all possible data sets. This can be easily carried out by Monte-Carlo simulation. For the purpose of the analysis presented here, measurement errors were assumed to be independent between years and between variables. The structure of the errors was defined as triangular distributions with a mode located at the point estimates currently used and ranging between a minimum and maximum representing $\pm X\%$ of the point estimates. Three levels of error were considered: $\pm 10\%$, $\pm 25\%$ and $\pm 50\%$. The same level of error was assigned to both the PFA and the lagged spawners as a preliminary approach. A total of 5,000 simulations were conducted for each level of error. It should be noted that accounting for measurement errors is different from considering autocorrelation in the data series which was not addressed in this analysis.

The results are summarized in Figure 5.7.2.1. Measurement errors can have major disruptive effects on the 1999 PFA forecast. As measurement errors increase, not only does the uncertainty of the prediction increase but also the most probable value. This is because the data are less informative about the variability in PFA than is assumed when no measurement errors are taken into account. As the predictive variables become less informative about PFA, the most probable value of the PFA approaches the mean. In a least squares regression sense, the slope of the relationship would decrease and the intercept would become more significant. If the independent variables were above their average level, which would lead to a high PFA forecast, the effect of the inclusion of measurement errors would be opposite. In both cases the accounting for measurement errors displaces the mode toward the average of the PFA series with increased uncertainty.

Part of the range of values of the PFA given in Figure 5.7.2.1 might be considered impossible given complimentary information available, such as observations of returns in homewaters over the last years. This can readily be introduced in the Bayesian analysis by means of a prior distribution of the PFA which would put a null probability *a priori* on implausible values. Even within a narrower range of possible values, it is impossible to assign contrasting levels of credibility to the PFA predicted values.

1. It is recommended that the extent of the measurement error inherent in the run-reconstruction model should be estimated to describe the potential bias in the mode and the description of uncertainty associated with the forecast.
2. The inclusion of the measurement error in the forecast model increases the uncertainty of the forecast and under increased uncertainty, alternative risk levels to the 50% point should be considered, consistent with the precautionary approach.
3. Other indices of adult salmon abundance should be examined and used as prior information to constrain the plausible range of abundance levels.
4. Alternative models should be explored (for example different predictive variables, model formulations, univariate time series, non-parametric change-of-state analyses,) to provide some index of plausibility of the quantitative forecasts.

5.7.3 Alternative models for characterizing salmon abundance

Two explanatory variables are presently used to model the prefishery abundance (PFA) of non-maturing 1SW salmon in the Northwest Atlantic before the Greenland fishery: spawning stock and environment (Section 5.6). The coefficients of the explanatory variables indicate that PFA is positively correlated with both the spawning stock size and the

environmental signal. PFA would be expected to decline as spawning stock and/or environment declines. In 1996 to 1998, PFA has declined, consistent with the decline in spawning stock but despite an improved environmental signal.

The spawning stock variable used in the model excludes the spawners from the Gulf and USA and therefore only considers part of the spawners contributing to PFA in the Northwest Atlantic. Also, the spawning stock variable only considers 2SW spawners while other age groups (1SW, 3SW and previous spawners) also contribute to egg depositions and undoubtedly salmon maturing as 2SW fish. Inclusion of all the spawning stock component from eastern North America is not a significant explanatory variable of PFA variability. The Gulf spawning stock has remained well above its area conservation requirement during the 1990s in contrast to other areas where spawning stock has declined.

A more useful variable for characterizing salmon abundance in the ocean would be an estimate of the annual smolt output from rivers of North America. If smolt output is known, factors determining mortality at sea could be explored directly using a standard survival relationship (Ricker 1975):

$$N_t/N_o = e^{-Z}$$

where N_t = population size at time t (for example PFA before West Greenland fishery)
 N_o = population size at an earlier time (for example smolt output)
 Z = instantaneous mortality rate

When stocks are exploited in fisheries, Z can be described in terms of the mortality due to the fishery (F) and due to natural mortality (M), i.e. $Z = F + M$. In the absence of fisheries (as is almost the case in the Northwest Atlantic for Atlantic salmon), Z is essentially equal to M .

Some of the factors contributing to natural mortality could be characterized by an environment signal (as in the currently used model) and predation (Section 2.4.6). The survival model with these two variables could be written (Hilborn and Walters 1992):

$$N_t/N_o = e^{-(\alpha \text{Pred} + \beta \text{Env} + c)}$$

where N_t and N_o are as previously defined
 Pred = variable measuring predator abundance (absolute or relative)
 Env = variable describing the environmental factor (absolute or relative)
 α = coefficient of the relative instantaneous mortality per unit predator
 β = coefficient of the relative instantaneous mortality per unit of environment
 c = constant proportional mortality

This formulation differs from the model currently used because the variables are considered to have a proportional effect on instantaneous mortality. For both variables, the relative instantaneous mortality is constant and independent of size of the salmon. But overall mortality is a function of relative levels of the variables. For example, as relative predator abundance increases, the overall mortality increases. But the relative change in mortality rates would decline as the variables increase. The relative change in mortality is always less than the relative change in the variables. In the absence of any predator or environment effect modifying survival, then survival is proportional to abundance.

The coefficients of the parameters could be estimated under a linear model assumption after transformation:

$$\ln(N_t/N_o) = -(c + \alpha \text{Pred} + \beta \text{Env}) + \varepsilon$$

where $\ln(\)$ refers to a natural logarithm transformation
 ε is the residual error, assumed $N(0, \sigma)$

A preliminary exploration of this model was undertaken using the data derived in other sections of the report. Since there are no estimates of total smolt production for the North American Commission area, a relative index of smolt production was determined using the smolt counts and juvenile surveys from the rivers in eastern Canada and USA (Section 4.2.1). Since 1971, the relative index of smolt production from eastern North America has increased by a factor of three with relative smolt production generally constant since 1986 (Figure 4.2.1.7).

PFA was considered as the sum of the maturing and non-maturing components to eastern North America (Table 4.2.3.3, 4.2.3.4). The predator index was the population size of harp seals in the Northwest Atlantic (Section 2.4.10). The environmental variable was the February habitat index in the Northwest Atlantic as described in Section 5.6.1 (Table 5.6.1.1).

PFA abundance is negatively associated with the index of relative smolt production from North America (Figure 5.7.3.1). Both February habitat index and predators are significantly correlated with the relative survival: habitat is

positively associated whereas predators are negatively correlated (Figure 5.7.3.2). When both the habitat and predator variables are included, the habitat variable becomes non-significant ($P > 0.5$). The year variable is also negatively correlated with the relative survival which should not be surprising since both the habitat index and the predator index are also significantly correlated whereas the relative smolt index is positively correlated (Figure 5.7.3.2). The absence of contrasting states in the variables examined inhibits the testing of alternative hypotheses to describe the observed declines in Atlantic salmon survival rates.

From this preliminary analysis, it can be concluded that:

1. the increased relative smolt production from North America has been insufficient to compensate for the increased mortality factors on Atlantic salmon;
2. the observed decline in relative survival associated with the increased relative smolt production is not sufficient to draw any conclusions on the nature of the mortality function, i.e., density dependent or density independent; and
3. in the absence of evidence for density-dependent mortality of Atlantic salmon at sea, the objective of achieving conservation in all salmon rivers of eastern North America remains valid.

5.8 Data Deficiencies and Research Needs in the WGC area

5.8.1 Progress on data deficiencies and research needs in the WGC area

Some progress was made on the recommendations for resolving data deficiencies and research requirements made in the 1998 report. First, the catch reporting system was improved for records of local sales and food fishermen over previous years. In order to improve the recording of local sales and food catches, individual fishermen were required to directly report their catches. However, in spite of these improvements, a relatively high proportion of the total food fishery catch is thought to have been unreported. Second, as the food fishery was spatially and temporally more diverse than the commercial fishery had been, the sampling programme in 1998 did not adequately cover the landings. The Working Group felt that further improvements in both catch statistics and sampling are required and accordingly reiterates last year's recommendations.

5.8.2 Recommendations for 1999

1. The mean weights, sea and freshwater ages and continent of origin are essential parameters to provide catch advice for the West Greenland fishery. As these parameters are known to vary over time, the Working Group recommends that the sampling programme, which occurred in 1995-98, be continued and improved to spatially and temporally cover as much of the landings as possible.
2. Efforts should be made to improve the estimates of the annual catches of salmon taken for local consumption at West Greenland.
3. The catch options for the West Greenland fishery are based almost entirely upon data derived from North American stocks (with the current exclusion of Labrador, see Section 4.6). In view of the evidence of a long-term decline in the European stock components contributing to this fishery (southern European non-maturing ISW recruits) the Working Group emphasised the need for information from these stocks to be incorporated into the assessments as soon as possible.
4. The bootstrapping approach to improve confidence intervals for the pre-fishery abundance forecast error estimates shows promise, and should be explored further.
5. The Working Group recommends that an evaluation be conducted on the present reliability of the PFA estimate. An initial approach is to determine what fraction of the PFA estimate is directly based on catches and assessed returns (hard data), and what fraction results from less certain information such as scaling factors for potential productive habitat.
6. It is recommended that the extent of the measurement error inherent in the run-reconstruction model should be estimated to describe the potential bias in the mode and the description of uncertainty associated with the forecast.
7. The inclusion of measurement error in the forecast model increases the uncertainty of the forecast and under increased uncertainty, alternative risk levels to the 50% point should be considered, consistent with the precautionary approach.
8. Other indices of adult salmon abundance should be examined and used as prior information to constrain the plausible range of abundance levels.
9. Alternative models should be explored (for example different predictive variables, model formulations, univariate time series, non-parametric change-of-state analyses) to provide some index of plausibility of the quantitative forecasts.

Table 5.1.1.1. Nominal catches of salmon, West Greenland 1960-98 (metric tons round fresh weight).

Year	Norway	Faroes	Sweden	Denmark	Greenland ¹	Total	Quota ²

1998	-	-	-	-	11	11	20 ¹⁰

¹ For Greenland vessels: all catches up to 1968 were taken with set gillnets only; after 1968, the catches were taken with set gillnets and drift nets. All non-Greenland catches 1969-75 were taken with drift nets.

² Quota figures apply to Greenland fishery only.

³ Figures not available, but catch is known to be less than Faroese catch.

⁴ Including 7 t caught on longline by one of two Greenland vessels in the Labrador Sea early in 1970.

⁵ The fishery was suspended.

⁶ Quota corresponding to specific opening dates of the fishery.

⁷ Quota for 1988-90 was 2,520 t with an opening date of 1 August and annual catches not to exceed the annual average (840 t) by more than 10%. Quota adjusted to 900 t in 1989 and 924 t in 1990 for later opening dates.

⁸ Set by Greenland authorities.

⁹ Quotas were bought out.

¹⁰ Fishery restricted to catches used for internal consumption in Greenland.

Figure 5.1.2.1 Numbers of North American and European Atlantic salmon caught at West Greenland 1982-92 and 1995-98.

Figure 5.3.1. Extant exploitation of the non-maturing component of North American salmon as 1SW salmon in North America and Greenland from the run reconstruction statistics.

Figure 5.6.1.1 Thermal habitat index for February and lagged spawners (SNLQ).

Figure 5.6.2.1. Bivariate relationships between independent variables lagged spawners (A) and thermal habitat (B) used in forecast model and pre-fishery abundance of non-maturing fish. Open symbol are for 1997 PFA.

Figure 5.6.2.2. Observed estimates, jackknifed historical predictions, and deterministic forecasts (A) of pre-fishery abundance. Residual pattern from jackknifed predictions (B).

Figure 5.6.2.3. Jackknifed predictions versus observed (A) and residuals versus observed (B) pre-fishery abundance. Open symbols, 1997.

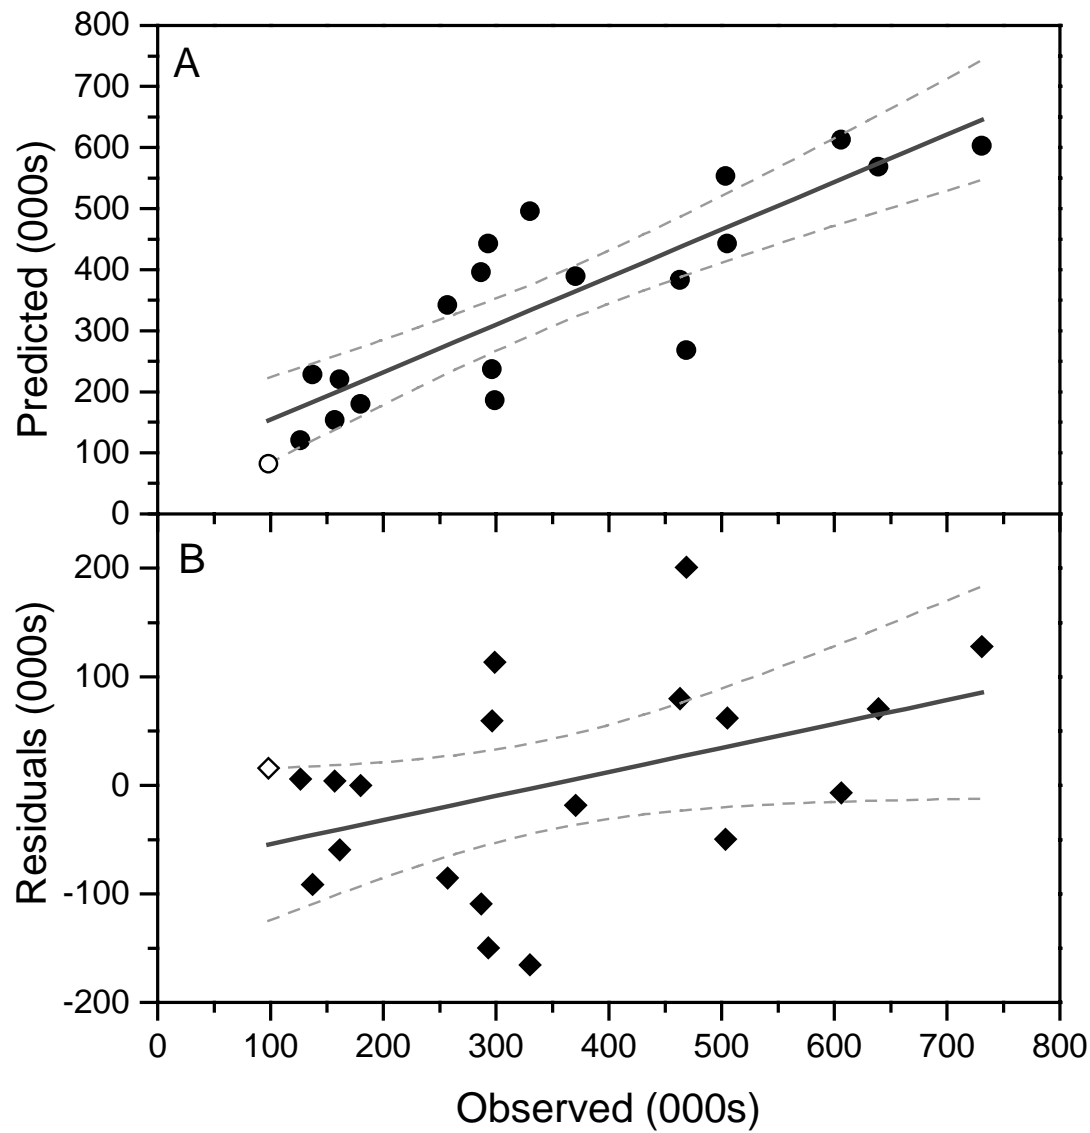

Figure 5.6.4.1. Theoretical risk analysis plots showing the risk-prone and risk-averse zones relative to the uncertainty of the stock assessment.

Figure 5.6.4.2. Distributions and probabilities of prefishery abundance forecasts for 1999 (upper panel), number of North American origin salmon captured in a 100 t fishery at West Greenland in 1999 (middle panel) and the post-fishery returns to North America in 2000 (bottom panel).

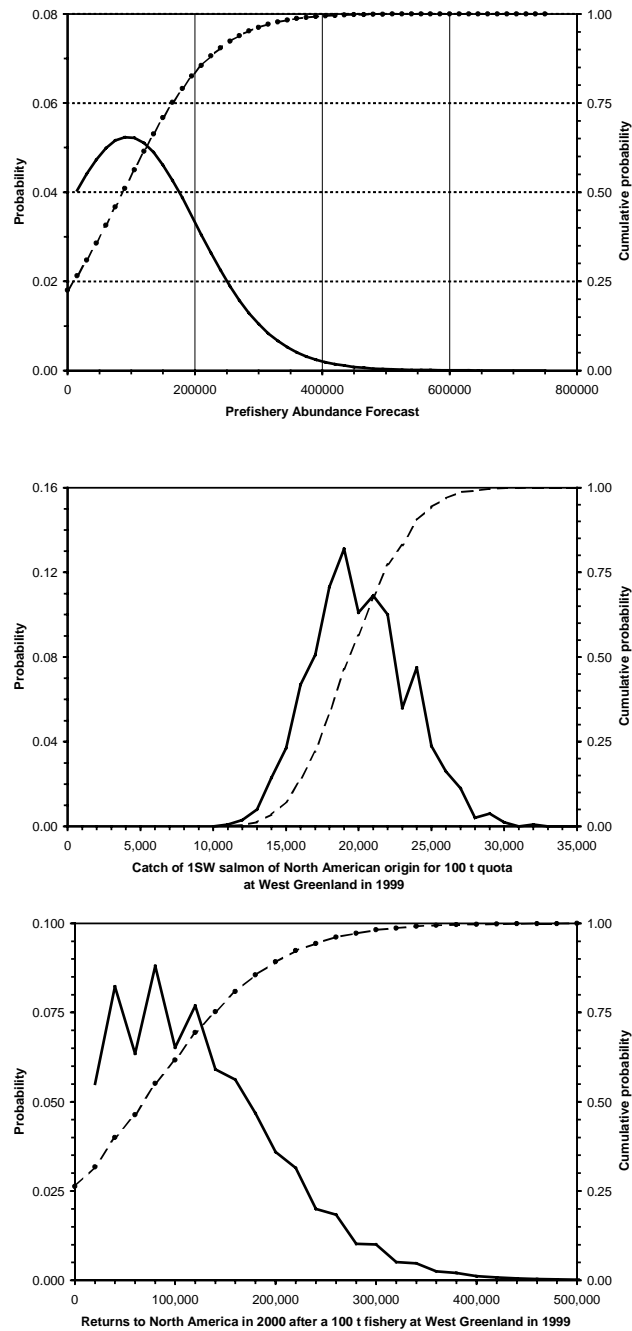

Figure 5.6.4.3. Summary of the distributions of the predicted biological characteristics of Atlantic salmon at West Greenland in 1999 generated from 1000 resampling events. The distribution of the weight of 1SW salmon of European origin is similar to the middle panel.

Figure 5.6.4.4. Risk analysis (probability of not meeting the conservation requirement in at least one of the six stock areas in North America) of catch options on the prefishery 1SW non-maturing salmon component in 1999. Risk is expressed relative to catch options at West Greenland in 1999 without fisheries in North America in 2000 (upper panel) and for combined fisheries at West Greenland in 1999 and North America in 2000 (lower panel). Exploitation rates in North America are based on levels varying between 0.15 and 0.25 on the returning large salmon (Section 4.1.4).

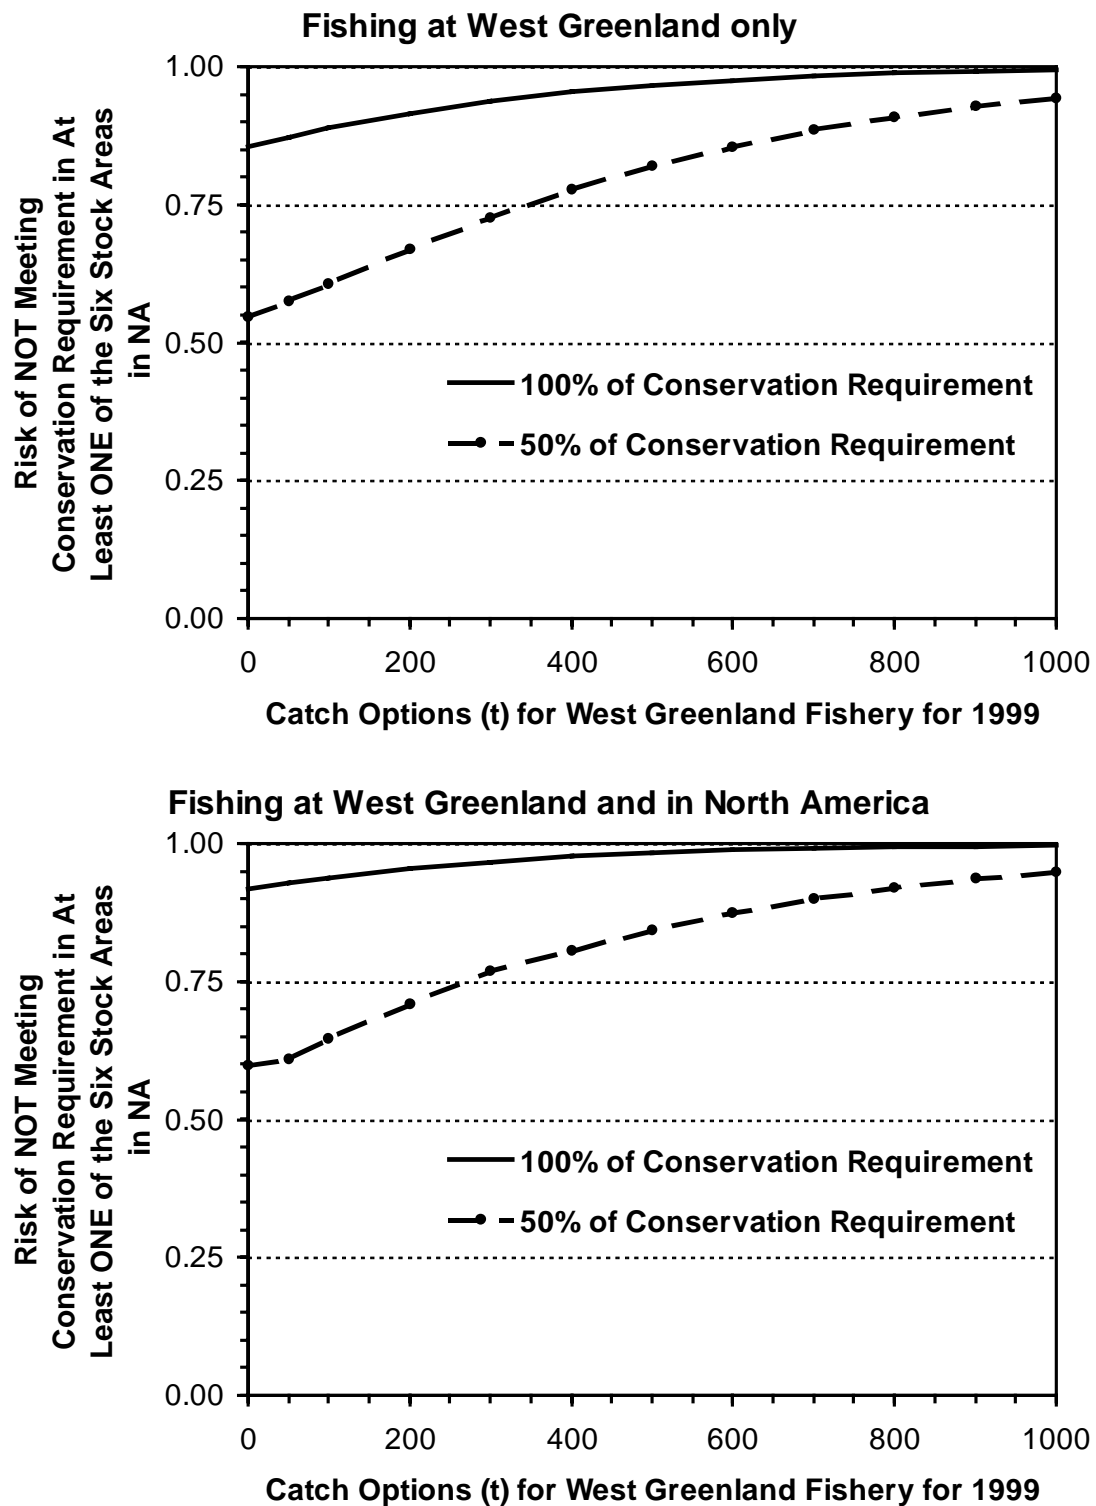

Figure 5.7.2.1. Approximate posterior predictive distributions (5000 Monte Carlo simulations) of the 1999 PFA under varying levels of measurement errors in the PFA and lagged spawner variables. The point estimate without error refers to the mode of the posterior predictive distribution.

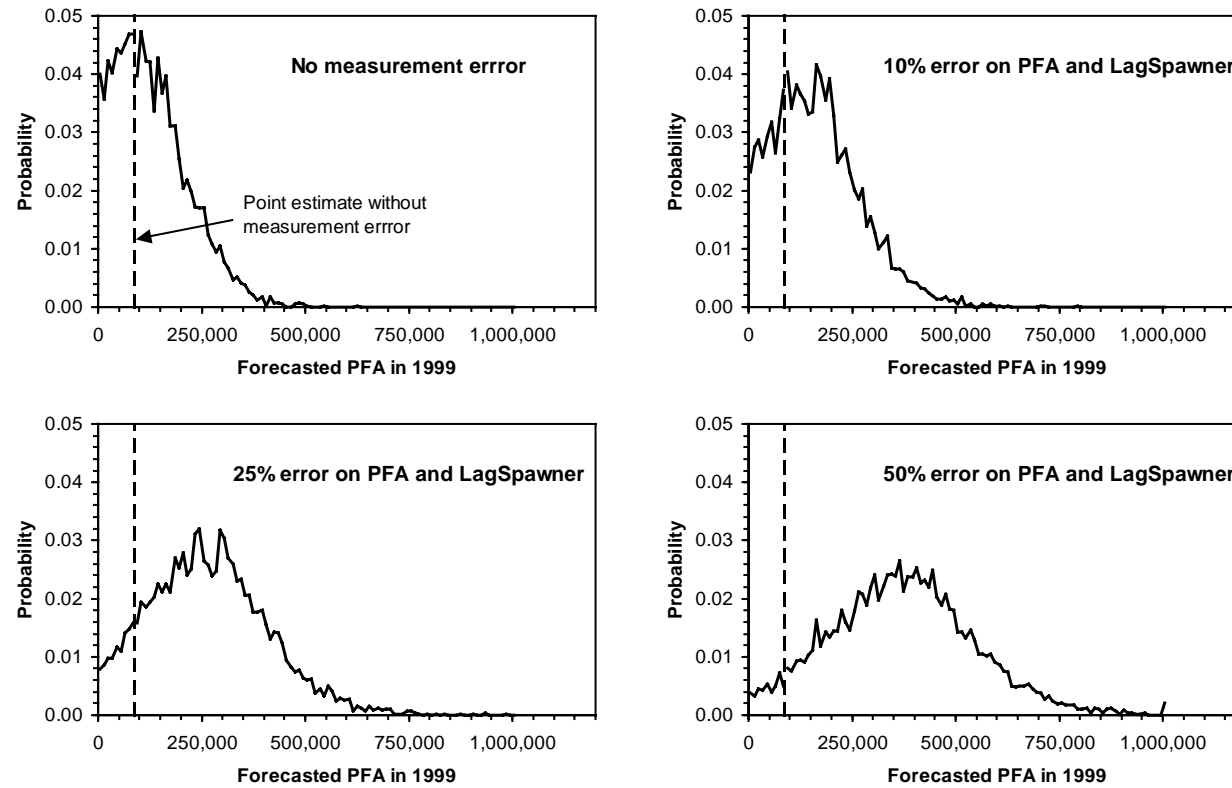

Figure 5.7.3.1. Relationship between estimated PFA of maturing and non-maturing 1SW salmon relative to the index of smolt production from North America (1972 to 1997).

Figure 5.7.3.2. Bivariate scatter plots of variables explored in the North American Atlantic salmon survival model. Variables are: LNSURV = \ln (maturing and non-maturing prefishery abundance relative to the area-weighted smolt index), FEBRUARY = index of habitat in February, SEALS98 = index of predator abundance based on harp seal population size, SMOLTS = area-weighted relative smolt index.

6 RECOMMENDATIONS

6.1 Meetings

The Working Group recommends that it should meet in 2000 to address questions posed by ACFM, including those posed by NASCO to ICES. To provide catch advice for West Greenland, the Working Group relies upon sea-surface temperature data which are complete by April 4. Therefore the Working Group should convene at ICES Headquarters on April 11.

6.2 Data Deficiencies and Research Needs

1. More research into the biology of salmon in the early marine phase is required and extension of recent research on the biology of post-smolts is recommended. Competitive interactions with other marine species should be explored. Additionally, by-catches of post-smolts in marine fisheries for other species should be monitored and estimates of mortality from this source should be derived. There is a continuing requirement to monitor trends in marine mortality for a wider range of stocks than at present, and to identify causes for current low levels of marine survival. In the latter context, it is noteworthy that an ICES Workshop on the Usefulness of Scale Growth Analyses and Other Measures of Condition in Salmon will be held in Amherst, USA in July, 1999.
2. It is recommended that a research fishery at Faroes should be continued and that material gained during previous study should continue to be worked-up.
3. The quality of data used to set conservation limits should continue to be improved and the PFA model should continue development. More and better input data should be obtained from a greater range of sources. Data collection should be targeted at finer scales. New ways of handling data, including GIS applications, and particularly new methods for grouping sub-divisions (eg., populations, or alternative divisions based on biological characteristics such as sea-age or run-timing) should continue to be explored, developed and validated. In particular, sensitivity analyses are essential to assess the confidence with which data derived from the theoretical models can be used in an applied management context.
4. Assessment methods for juvenile salmon and for freshwater habitat parameters should continue to be developed. Attempts should be made to couple these parameters with adult return parameters, via life-history models of appropriate scale. Habitat and life-history variables should be used together to examine the extent to which stock-recruitment relationships from a limited range of index rivers are transferable to other rivers.
5. The status of southern and central European rivers with respect to *Gyrodactylus* species, and particularly *G. salaris*, should be established without delay. Monitoring of the spread and occurrence of *G. salaris* should be encouraged in salmon-producing countries, and in other countries that are possible sources for transfer of the parasite.
6. There is an urgent need to monitor salmon returns and develop habitat-based spawner requirements in Labrador and Ungava regions of Québec.
7. There is a need to investigate changes in the biological characteristics (mean weight, sex ratio, sea-age composition) of returns to rivers, spawning stocks, and total recruits prior to fisheries. These data and new information on measures of habitat and stock recruitment are necessary to re-evaluate existing estimates of spawner requirements in Canada and USA.
8. There is a requirement for additional smolt-to-adult survival rates for wild salmon. As well, sea survival rates of wild salmon from rivers stocked with hatchery smolts should be examined to determine if hatchery return rates can be used as an index of sea survival of wild salmon elsewhere.
9. Further basic research is needed on the spatial and temporal distribution of salmon and their predators at sea to assist in explaining variability in survival rates.
10. The mean weights, sea and freshwater ages and continent of origin are essential parameters to provide catch advice for the West Greenland fishery. As these parameters are known to vary over time, the Working Group recommends that the sampling programme, which occurred in 1995-98, be continued and improved to spatially and temporally cover as much of the landings as possible.
11. Efforts should be made to improve the estimates of the annual catches of salmon taken for local consumption at West Greenland.

12. The catch options for the West Greenland fishery are based almost entirely upon data derived from North American stocks. In view of the evidence of a long-term decline in the European stock components contributing to this fishery (southern European non-maturing 1SW recruits) the Working Group emphasised the need for information from these stocks to be incorporated into the assessments as soon as possible.
13. The bootstrapping approach to improve confidence intervals for the pre-fishery abundance forecast error estimates shows promise, and should be explored further.
14. The Working Group recommends that an evaluation be conducted on the present reliability of the PFA estimate. An initial approach is to determine what fraction of the PFA estimate is directly based on catches and assessed returns (hard data), and what fraction results from less certain information such as scaling factors for potential productive habitat.
15. It is recommended that the extent of the measurement error inherent in the run-reconstruction model should be estimated to describe the potential bias in the mode and the description of uncertainty associated with the forecast.
16. The inclusion of measurement error in the forecast model increases the uncertainty of the forecast and under increased uncertainty, alternative risk levels to the 50% point should be considered, consistent with the precautionary approach.
17. Other indices of adult salmon abundance should be examined and used as prior information to constrain the plausible range of abundance levels.
18. Alternative models should be explored (for example different predictive variables, model formulations, univariate time series, non-parametric change-of-state analyses) to provide some index of plausibility of the quantitative forecasts.

APPENDIX 1

WORKING DOCUMENTS SUBMITTED TO THE WORKING GROUP ON NORTH ATLANTIC SALMON, 1999

- Doc. No. 1 Friedland, K. and R. Brown. Forecast estimate of North American stock abundance using bootstrapping techniques.
- Doc. No. 2 Friedland, K.D. and D.G. Reddin. Production patterns and thermal conditions in Atlantic salmon post-smolt nurseries in the northwest Atlantic area.
- Doc. No. 3 Reddin, D.G., J.B. Dempson, P. Downton, C.C. Mullins and K.D. Friedland. Migration of Atlantic salmon kelts (*Salmo salar*) in relation to sea water temperature in Newfoundland, 1998.
- Doc. No. 4 Reddin, D.G. Return and spawner estimates Atlantic salmon for insular Newfoundland.
- Doc. No. 5 Reddin, D.G., Estimation of the Labrador component of prefishery abundance of North American Atlantic salmon (*Salmo salar*) in 1998.

Appendix 4. Eggs taken and juvenile Atlantic salmon and eggs stocked (excluding private commercial sea ranching).

Blank fields indicate data not available.

Estimated number (nearest 1,000) of eggs spawned by artificial methods from (Year) sea-run adults in autumn/winter period of Year / Year +1).

Example = eggs artificially spawned and recorded for 1997 were spawned during the fall/winter period of 1997/1998

Country / Year	Total Eggs Artificially Spawned	Eggs Stocked (rounded to nearest 1,000)			No. Fry Stocked (rounded to nearest 1,000)			No. Parr Stocked (rounded to nearest 100)				No. Smolts (rounded to nearest 100)		
		Green	Eyed	All	Unfed	Fed	All	0+	1 & 1+	2 or >	All	1	2 or more	All

Comments:

- (1) All eggs and juveniles stocked are obtained from foreign eggs (french, irish, scottish) which are reared in hatchery in Belgium
 (2) Parr stocked : parr 0+ from 50 to 100 mm, with a majority of 50 mm

Comments:

- (1) Total eggs artificially spawned includes some egg collections from captive sea run kelts.
 (2) Eggs artificially spawned, 1990-1996, incomplete; eggs and unfed fry in 1997 are provisional.

Comments

- (1) 1992 data are incomplete
- (2) 1990, 1991, and 1998 data are currently unavailable.
- (3) In addition, 195300, 73733, 22000, and 150 Atlantic salmon of unspecified life stages were released from 1993 to 1996, respectively.

Comments:

(1) Total Eggs Artificially Spawmed include only eggs collected from sea-run fish. Significant numbers of eggs are also collected from captive/broodstock and captive sea-run kelts.

Estimates are based on:

EST SMALL RETURNS = (COMM CATCH*PROP LAB ORIGIN)/EXP RATE, PROP SFA_{1,2&14B}=.6-.8, SFA 1.0.36-0.42&SFA 2.0.75-0.85(97) EXP RATE-SFA_{1,2&14B}=.3-.5(89-91), .22-.39(92), .13-.25(93),
 -.10-.18(94), .07-.13(95), .04-.07(96), SFA 1.0.07-0.14&SFA 2.0.04-0.07 (97)

EST GRILSE RETURNS CORRECTED FOR NON-MATURING 1SW - (SMALL RET*PROP GRILSE), PROP GRILSE SFA_{1,2&14B}=0.8-0.9

EST RET TO FRESHWATER - (EST GRILSE RET-GRILSE CATCHES)

EST GRILSE SPAWNERS = EST GRILSE RETURNS TO FRESHWATER - GRILSE ANGLING CATCHES

*Catches for 1969-73 are Labrador totals distributed into SFAs as the proportion of landings by SFA in 1974-78.

Furthermore small catches in 1973 were adjusted by ratio of large:small in 1972&74 (SFA 1-1.4591, SFA 2-2.2225, SFA 14B-1.5506).

**Preliminary values adjusted for change in size category

WAG - are North American 15W salmon of river age 4 and older of which 70% are Labrador origin

EST 25W SPANNERS = EST 25W RETURNS TO FRESHWATER = 25W ANGLING CATCHES

MCatches for 1969-73 are Labrador totals distributed into SEAs as the proportion of landings by SEA in 1974-78.

**1997 Preliminary values adjusted for size category

Appendix 6(iii). Atlantic salmon returns to freshwater, total recruits prior to the commercial fishery and spawners summed for Salmon Fishing Area 3-14A, Insular Newfoundland, 1969-1998.
Ret. = retained fish; Rel. = released fish.

Year	Small catch		Small returns to river		Small recruits		Small spawners		Large returns to river		Large recruits		Large catch		Large spawners		2SW returns to river		2SW spawners		2SW recruits

SRR (Small returns to river) are the sum of Bay St. George small returns (Reddin & Mullins 1986) plus Humber R small returns (Mullins & Reddin 1986) plus small returns in SFAs 3-12 & 14A.

SSR (Small recruits) = SRR*(1-Exploitation rate commercial (ERC)) where ERC=0.5-0.7, 1989-91 & ERC=0, 1992-98.

SS (Small spawners) = SSR*(SC*(SR*0.1))

SC = small salmon catch retained

SR = small salmon catch released with assumed mortalities at 10%

RL (Ratio large small) are from counting facilities in SFAs 3-11, 13 & 14A, angling catches in SFA 12.

LR (Large returns to river) = SRR * RL

LR (Large recruits) = LRR*(1-Exploitation rate large (ERL)), where ERL=0.7-0.9, 1989-91; & ERL=0, 1992-98.

LS (Large spawners) = LRR-large catch retained (LC-H) 0.1*large catch released

2SW-RR (2SW returns to river) = LR*proportion 2SW of 0.4-0.6 for SFAs 12-14A & 0.1-0.2 for SFAs 3-11.

2SW-S (2SW spawners) = LS * proportion 2SW of 0.4-0.6 for SFAs 12-14A & 0.1-0.2 for SFAs 3-11.

2SW-R (2SW recruits) = LR * proportion 2SW of 0.4-0.6 for SFAs 12-14A & 0.1-0.2 for SFAs 3-11.

Return and spawner estimates for SFA 15 are based on Restigouche River data, scaled up for SFA 15 using angling data.

Restigouche stock assessment is based on angling catch with assumed exploitation rates between 50% (min.) and 30% (max).

The proportion of 2SW in large salmon numbers is based on aged scale samples from angling, trapnets, and broodstock.

No scale samples were available for 1970-71, 1995-96: the mean value of 0.65 is used here.

Salmon in the Quebec portions of the Restigouche River were subtracted from the total for the watershed.

The returns and spawners estimates thus derived for the SFA 15 portion of the Restigouche were then multiplied by the minimum (1.117) and maximum (1.465) ratios of angling catch in SFA15:SFA 15 portion of Restigouche catch to obtain estimates for SFA 15.

Returns to the Miramichi are from the assessment. Min. and max values are based on capture efficiencies of Millbank trapnet which gave a lower CI of -20% of estimate and upper CI of 33% of estimate.

For 1992 and 1993, lower and upper CI are based on estimate bounds of -18.5% to +18.5%.

For 1994 to 1997, min and max are 5th and 95th percentiles from the assessment.

Prop. 2SW are from scale ageing.

Miramichi makes up 91% of total rearing area of SFA 16.

Returns to SFA 16 are Miramichi returns / 0.91 or (Min., Max.) 2SW returns to Miramichi / 0.91

Same procedure for escapements as used to calculate returns.

Escapement of 2SW to SFA 16			Escapements to the Miramichi River						Escapement of large salmon to SFA 16

Returns to the Miramichi are from the assessment. Min. and max values are based on capture efficiencies of Millbank trapnet which gave a lower CI of -20% of estimate and upper CI of 33% of estimate.

For 1992 and 1993, lower and upper CI are based on estimate bounds of -18.5% to +18.5%.

For 1994 to 1997, min and max are 5th and 95th percentiles from the assessment.

Prop. 1SW are from scale ageing. Proportions vary from 0.97 to 1.00. Ref. Moore et al. 1995.

Miramichi makes up 91% of total rearing area of SFA 16.

Returns to SFA 16 are Miramichi returns / 0.91 or (Min., Max.) 1SW returns to Miramichi / 0.91

Same procedure for escapements as used to calculate returns.

Year	Escapement of 1SW to SFA 16		Escapement to the Miramichi			Prop. 1SW	Escapement of 1SW

Notes

CPU is retained catch per rod-day.

In the above table a period indicates no data.

Retained fish include native harvest and estimated hook-and-released mortality

Size of angled salmon was not recorded in 1955-1969. Numbers of small and large salmon for these years are estimated from the overall small:large ratio for 1970-1980.

Number of small retained salmon in 1993 was not recorded. The number given is the mean for 1988-1992

For 1950-1969, percent small is the percent measured in 1970-1980. For 1970-1980, percent small is calculated from numbers of small and large salmon in the retained catch in each year. For 1981-1997, percent small is calculated from numbers of small and large salmon taken at the Leard's Pond trap. For 1998, percent small is taken from seining catches at Mooneys Pool.

Small recruits are calculated as small retained salmon/exploitation rate. Angler exploitation was calculated as 0.34, 0.347, and 0.264 of estimated returns in 1994, 1995, and 1996, respectively. For other years the mean of these values is used. The min and max numbers of small recruits are calculated using max numbers of small recruits are calculated using exploitation + or - 0.1; e.g. 0.34 + or - 0.1 gives 0.24 and 0.44.

Small spawners = number of small recruits - number of small retained

Large recruits = (number of small recruits/(0.01*percent small)) - number of small recruits

Large spawners = number of large recruits - number of large retained

It is assumed that large salmon and 2SW salmon are equivalent

Small spawners = number of small recruits - number of small retained

Large recruits = (number of small recruits/(0.01*percent small)) - number of small recruits

Large spawners = number of large recruits - number of large retained

It is assumed that large salmon and 2SW salmon are equivalent

Appendix 6(viia). Total 2SW returns and spawners to SFA 18, 1970-1998.

Margaree returns, 1970-84, equal catch (min 0.215) or max (0.37) exploitation rate.

Return of large salmon (MIN) and (MAX) to all SFA 18 equals Margaree returns * ratio Margaree catch to SFA 18 catch.

Margaree returns 1984-1998 based on various Margaree CAFSAC, DFO Atl. Res. and CSAS Res. Docs.

Margaree catch to SFA 18 catch; MIN_MAX 2SW based on the ratio 0.77-0.87 2SW fish among MSW fish.

Margaree escapements 1970-1983 = returns minus removals; 1984-1998 from various Margaree CAFSAC, DFO Atl. Fish. and CSAS Res.

Docs e.g., Marshall et al. (MS 1988) 2SW equal 0.77-0.87 of MSW fish; Margaree raised to SFA by respective ratios in sport catch.

240

Appendix 6(viib). Total 1SW returns and spawners to SFA 18, 1970-1998.

Max	2.378

Margaree returns, 1970-83, equal catch divided by MIN (0.215) and MAX (0.37) exploitation rate. Return of small salmon to all SFA 18 equals Margaree returns * MIN and MAX ratio of Margaree catch to SFA 18 catch. Margaree returns, 1984-1998, based on annual assessments in CAFSAC and DFO Atl. Fish. and Can. Sec. Assess.Stocks Res. Docs, eg., Marshall et al. (MS 1998). Spawners for 1970-1983 equal returns minus removals; 1984-1996 from various Margaree CAFSAC, Atl. Res. and CSAS Res Doc. series, eg., Marshall et al. (MS 1998).

Appendix 6(viii). Total 1SW returns and spawners, SFAs 19, 20, 21 and 23, 1970-1998.

SFAs 19,20,21: Returns estimated as run size (1SW recreational catch / expl. rate [0.2-0.45], where MIN and MAX selected as 5th and 95th percentiles values from 1,000 monte carlo estimates) + estimated 1SW fish in commercial landings 1970-1993 (Cutting et al. MS 1985).

SFA 22: Inner Fundy stocks and inner-Fundy SFA 23 (primarily 1SW fish) do not go to the North Atlantic.

SFA 23: Similar approach as for SFAs 19-21 except that estimated wild 1SW returns destined for Mactaquac Dam, Saint John River, replaced values for recreational catch and estimated proportions that production above Mactaquac is of the total (0.4-0.8) river replaced exploitation rates, Marshall (MS 1992) (commercial harvest, bi-catch etc., incl. in estimated returns); hatchery returns attributed to above Mactaquac only; 1SW production in rest of SFA (outer Fundy) omitted

a- Revision of method, SFA 23, 1993-1998, estimated returns to Nashwaak fence raised by proportion of area below Mactaquac (0.21-0.30) and added to total estimated returns originating upriver of Mactaquac (Marshall et al. 1998b). MIN and MAX removals below Mactaquac based on Nashwaak losses, Mactaquac losses are a single value and together summed and removed from returns to establish estimate of spawners.

SFAs 19-21, estimate of returns for 1998 based on regression of Lohave wild counts on MIN and MAX estimates of total SFA 19-21 returns.

1984-1997, because there was no angling in SFAs 20-21 in 1998.

Values in SFAs 19-21, revised from previous year using final estimates of recreational catch for 1997.

1998	>>>																			

Scavengers = returns minus removals where:

*'Returns' are from App. 5(xa), where revisions to methods for SFAs 19-21, 1998, and SFA 23 1993-1998 are outlined (1997 values for SFAs 19-21 revised on basis of final estimate of recreational catch).

removals" of 25W fish in SFAs 19-21 have been few, largely illegal and unascertained since the catch-and-release andling regulations in 1985; removals in SFA 23

1985-1987 had been in total the assessed losses to stocks originating above Mactaquac. The revised method (App. 5 (iii)), 1993-1998 incorporates 5th and 95th percentile values for losses noted on the Nashveak raised to the total production area downstream of Mactaquac and the previously assessed and used values for stocks upstream of Mactaquac.

Appendix 6 x. Global evaluation of the number of recruits and spawners for all the Quebec's river, 1969-1998.

APPENDIX 7

COMPUTATION OF CATCH ADVICE FOR WEST GREENLAND

The North American Spawning Target (SpT) for 2SW salmon has been revised to 180,495 fish in 1996.

This number must be divided by the survival rate for the fish from the time of the West Greenland fishery to their return of the fish to home waters (11 months) to give the Spawning Target Reserve (SpR). Thus:

$$\text{Eq. 1. } \text{SpR} = \text{SpT} * (\exp(11 * M)) \quad (\text{where } M = 0.01)$$

The Maximum Allowable Harvest (MAH) may be defined as the number of non-maturing 1SW fish that are available for harvest. This number is calculated by subtracting the Spawning Target Reserve from the pre-fishery abundance (PFA).

$$\text{Eq. 2. } \text{MAH} = \text{PFA} - \text{SpR}$$

To provide catch advice for West Greenland it is then necessary to decide on the proportion of the MAH to be allocated to Greenland (f_{NA}). The allowable harvest of North American non-maturing 1SW salmon at West Greenland (NA1SW) may then be defined as

$$\text{Eq. 3. } \text{NA1SW} = f_{\text{NA}} * \text{MAH}$$

The estimated number of European salmon that will be caught at West Greenland (E1SW) will depend upon the harvest of North American fish and the proportion of the fish in the West Greenland fishery that originate from North America [PropNA]¹. Thus:

$$\text{Eq. 4. } \text{E1SW} = (\text{NA1SW} / \text{PropNA}) - \text{NA1SW}$$

To convert the numbers of North American and European 1SW salmon into total catch at West Greenland in metric tonnes, it is necessary to incorporate the mean weights (kg) of salmon for North America [WT1SWNA]¹ and Europe [WT1SWE]¹ and age correction factor for multi-sea winter salmon at Greenland based on the total weight of salmon caught divided by the weight of 1SW salmon [ACF]¹. The quota (in tonnes) at Greenland is then estimated as

$$\text{Eq. 5. } \text{Quota} = (\text{NA1SW} * \text{WT1SWNA} + \text{E1SW} * \text{WT1SWE}) * \text{ACF}/1000$$

¹ New sampling data from the 1995 fishery at West Greenland were used to update the forecast values of the proportion of North American salmon in the catch (PropNA), mean weights by continent [WT1SWNA, WT1SWE] and the age correction factor [ACF] in 1996.
