## 19 Golden redfish (Sebastes norvegicus) in subareas 5, 6 and 14

### 19.1 Stock description and management units

Golden redfish (Sebastes norvegicus) in ICES subareas 5 and 14 have been considered as one management unit. Catches in ICES Subarea 6 have traditionally been included in this report and the group continues to do so. Data from ICES Subarea 6 is, however, not used in the assessment.

### 19.2 Scientific data

This section describes results from various surveys conducted annually on the continental shelves and slopes of ICES subareas 5 and 14 .

### 19.2.1 Division 5.a

Two bottom trawl surveys are conducted in Icelandic waters, the Icelandic spring groundfish survey (spring survey) and the Icelandic autumn groundfish survey (autumn survey). The spring survey has been conducted annually in March since 1985 and the autumn survey has been conducted annually in October since 1996. The autumn survey was not conducted in 2011. Description of the Icelandic bottom trawl surveys and the calculation of the survey indices for golden redfish in ICES 5.a. are given in the Stock Annex (smr-5614 SA). The calculation of the survey indices includes length dependent diel vertical migration of the species.

Two survey indices are calculated from these surveys but only the index from the spring survey is used in the assessment of golden redfish. Length disaggregated indices from the spring survey are used in the Gadget model. Age-length keys from the autumn survey in 2 cm length groups are used in the Gadget model.

The total biomass of golden redfish as observed in the spring survey decreased from 1988 to a record low in 1995 (Figure 19.2.1 and Table 19.2.1). From 2000 to 2016 the biomass increased, with some fluctuation, to the highest value in the time-series. Since then, the index has decreased and was in 2019-2021 similar as in 2014 and 2015. The CV of the measurement error has been considerably higher after 2002.

The total biomass index from the autumn survey shows similar trend as in the spring survey when the index gradually increased from 2000 to the highest value in the time series in 2014 . The total biomass index in 2015-2019 fluctuated around the 2014 level but decreased sharply in 2020 (Figure 19.2.1 and Table 19.2.1).
Length disaggregated indices from the spring survey shows that the peaks in length $4-11 \mathrm{~cm}$, which can be seen first in 1987 (the 1985 cohort) and then in 1991-1992 (the 1990 cohort), reached the fishable stock approximately 10 years later (Figure 19.2.2). The increase in the survey index between 1995 and 2005 reflects the recruitment of these two strong year classes. During the 1999-2008 period the abundance of small redfish was lower than in 1986-1990, highest in 20002003 (Figure 91.2.1). In 2009-2021, very little of small redfish has been observed in the spring survey (Figure 19.2.1). In recent years, the modes of the length distribution in both surveys have shifted to the right and is narrower. The abundance of golden redfish smaller than 30 cm has decreased since 2006 in both surveys and is now at the lowest level in the time-series (Figures 19.2.1, 19.2.2 and 19.2.3).

Age disaggregated abundance indices from the autumn survey are shown in Figure 19.2.4 and in Table 19.2.2. The sharp increase in the survey indices since 2005 reflects the recruitment of the year-classes from 1996-2007. The year-classes 1996-2002 are gradually disappearing from the stock and the 2003-2008 year-classes are now the most abundant year-classes in the stock. The age disaggregated abundance indices indicate that all year-classes since 2009 are small.

### 19.2.2 Division 5.b

In Division 5.b, CPUE of golden redfish were available from the Faeroes spring groundfish survey from 1994-2021 and the summer survey 1996-2020 (see smr-5614 SA). Both surveys show similar trends in the indices from 1998 onwards with sharp declines between 1998 and 1999 (Figure 19.2.5). CPUE in the spring survey since 2000 has been stable at low level. The CPUE index in the summer survey shows similar trend as in the spring survey and has gradually decreased and is at the lowest level recorded.

### 19.2.3 Subarea 14

The German groundfish survey has been conducted annually in the autumn from 1982 to 2017 and in 2019-2020 covering shelf areas and the continental slopes off West and East Greenland. Description of the survey and the re-stratification in 2013 is found in the Stock Annex (smr5614 SA). In 2017, sampling was only conducted in parts of East Greenland and one spot in NAFO 1F with a total of 46 stations. This is low compared to necessary coverage of $63-75$ stations in the respective area as done in the previous years. The survey was not conducted in 2018 because of research vessel breakdown.

Relative abundance and biomass indices for golden redfish (fish $>17 \mathrm{~cm}$ ) from the German groundfish survey are illustrated in Figure 19.2.6. After a severe depletion of the golden redfish stock on the traditional fishing grounds around East Greenland in the early 1990s, the survey estimates showed a significant increase from 2003, both in biomass and abundance (Figure 19.2.6). The survey indices in 2007-2017 were high but fluctuated. The biomass survey index in 2014-2016 were at the highest level in the time-series but decreased in 2017-2020 to similar level as in 2006 (Figure 19.2.6a). It should be noted that the CV for the indices is high and the increase is driven by few very large hauls. In 2010-2020, the biomass of pre-fishery recruits ( $17-30 \mathrm{~cm}$ ) has decreased compared to previous five years and in 2017-2020 very little of 17-30 cm fish was observed (Figure 19.2.6c).

Abundance indices of redfish smaller than 18 cm from the German annual groundfish survey show that juveniles were abundant in 1993 and 1995-1998 (see Figure 18.2.1). Since 2008, the survey index has been very low and in recent years at the lowest value recorded since 1982. Juvenile redfish were only classified to the genus Sebastes spp., as species identification of small specimens is difficult due to very similar morphological features. The 1999-2020 survey results indicate low abundance and are like those observed in the late 1980s. The Greenland shrimp and fish shallow water survey 2008-2020 (no survey conducted 2017-2019) also shows very little juvenile redfish ( $<18 \mathrm{~cm}$, not classified to species) were present (see Figure 23.2.6).

### 19.3 Information from the fishing industry

### 19.3.1 Landings

Total landings of golden redfish decreased gradually by more than $70 \%$ in 1982-1994 or from 130429 t in 1982 to 43515 t in 1994 (Table 19.3.1 and Figure 19.3.1). Since then, the annual landings
of the stock have varied between 33451 t and 59698 t . The total landings in 2020 were 45893 t , which is 2753 t less than in 2019. About $90-98 \%$ of the golden redfish catch has been taken in Icelandic Waters (ICES Division 5.a).

Landings of golden redfish in Division 5.a (Icelandic waters) declined from 97899 t in 1982 to 38 669 t in 1994 (Table 19.3.1). Since then, landings have varied between 31686 t and 54041 t , highest in 2016. The annual landings since 2016 have decreased and were 40688 t in 2020, 4058 t less than in 2019. The landings were $5 \%$ higher than allocated quota of 38896 t . The reasons for the implementation errors are related to the management system that allow for transfers of quota share between fishing years and conversion of TAC from one species to another. Detailed description of the Icelandic ITQ system is found in the Stock Annex for the species (smr-5614 SA).

Between $90-95 \%$ of the golden redfish catch in Division 5.a is taken by bottom trawlers targeting redfish. The remaining catches are caught as bycatch in the gillnet, long-line, and lobster fisheries. In 2020, as in previous years, most of the catches were taken along the shelf southwest, west, and northwest of Iceland (Figure 19.3.2). Higher proportion of the catches is now taken along the shelf northwest of Iceland and less south and southwest.

In Division 5.b (Faroese waters), annual landings decreased from 9194 t in 1985 to less than 700 t in the 2006-2016 period (Table 19.3.1). In 2017 landings increased to 1397 t , the highest landings since 2005. The landings in 2020 was 1297 t . Most of the golden redfish caught in Division 5.b is taken by pair and single trawlers (vessels larger than 1000 HP ).

In Subarea 14 (East Greenland waters), the landings of golden redfish reached a record high of 30962 t in 1982 but decreased drastically within the next three years and to 2117 t in 1985 (Figure 19.3.1 and Table 19.3.1). During the period 1985-1994, the annual landings varied between 687 and 4255 t . There was little or no direct fishery for golden redfish from 1995 to 2009 and landings were 200 t or less, mainly taken as bycatch in the shrimp fishery. In 2010, landings of golden redfish increased considerable and were 1650 t . This increase is mainly due to increased S. mentella fishery in the area. Annual landings 2010-2015 have been between 1000 t and 2700 t but increased to 5442 t in 2016 which is the highest landings since 1983. The landings in 2020 were 4105 $\mathrm{t}, 1440 \mathrm{t}$ more than in 2019.

Annual landings from Subarea 6 increased from 1978 to 1987 followed by a gradual decrease to 1992 (Table 19.3.1). From 1995 to 2004, annual landings have ranged between 400 and 800 t, but decreased to 137 t in 2005. Little or no landings of golden redfish were reported from Subarea 6 in 2006-2020 and were 100 t in 2020.

### 19.3.2 Discard

Comparison of sea and port samples from the Icelandic discard sampling program does not indicate significant discarding due to high grading in recent years (Pálsson et al 2010), possibly due to area closures of important nursery grounds west off Iceland. Substantial discard of small redfish took place in the deep-water shrimp fishery from 1986 to 1992 when sorting grids became mandatory. Since then, the discard has been insignificant both due to the sorting grid and much less abundance of small redfish in the region.

Discard of redfish species in the shrimp fishery in ICES Division 14.b is currently considered insignificant (see Section 18).

### 19.3.3 Biological data from commercial fishery

The table below shows the fishery related sampling by gear type and ICES divisions in 2020. Sampling in 5.a was in 2020 considerably less than in previous years because of the COVID-19.

| Area | Nation | Gear | Landings (t) | Samples | No. length measured | No. Age read |
| :--- | :--- | :--- | :---: | :---: | :---: | :---: |
| 5.a | Iceland | Bottom trawl | 40688 | 65 | 9191 | 834 |
| 5.b | Faroe Islands | Bottom trawl | 1297 | 116 |  |  |
| 14 | Greenland | Bottom trawl | 4105 |  |  |  |

### 19.3.4 Landings by length and age

The length distributions from the Icelandic commercial trawler fleet in 1976-2020 show that most of the fish caught is between 30 and 45 cm (Figure 19.3.3). The modes of the length distributions range between 35 and 40 cm and has over the past decade shifted to the right. The length distributions in 2012-2020 are narrower than previously, with less than average of small fish ( $<35 \mathrm{~cm}$ ) caught, and the mean length has increased by almost 4 cm .

Catch-at-age data from the Icelandic fishery in Division 5.a show that the 1985-year class dominated the catches from 1995-2002 (Figure 19.3.4 and Table 19.3.2). The strong 1990 cohort dominated the catch in 2003-2007 contributing between $25-30 \%$ of the total catch in weight. In 20072010 the 1996-1999 cohorts dominated in the catches but are now gradually decreasing. The 2003-2008 cohorts (ages 12-17) were the most dominant year classes in the fishery in 2020. There is a substantial decrease of 7-10-year-old fish in the catch, compared to recent previous years, an additional indicator of low recruitment in recent year observed in all surveys conducted in East Greenland and Icelandic waters.

The average total mortality $(Z)$, estimated from the 25-year series of catch-at-age data (Figure 19.3.5) is about 0.20 for age 13 years and older.

Length distribution from the Faroese commercial catches 2001-2020 shows that the fish caught are on average larger than 40 cm with modes between 45 cm and 50 cm (Figure 19.3.6).

No length data from the catches in subareas 14 and 6 have been available for several years.

### 19.3.5 CPUE

The un-standardized CPUE index from the Icelandic bottom trawl fleet operating in Division 5.a has increased sharply since 2006 and is at the highest level in the time-series. Effort towards golden redfish has gradually decreased since 1986 and is now at the lowest level recorded (Figure 19.3.7). CPUE derived from logbooks is not considered indicative of stock trends however the information contained in the logbooks on effort, spatial and temporal distribution the fishery is of value.

CPUE from other areas are not available. This is because no separation of S. norvegicus/S. mentella is made in the catches.

### 19.4 Analytical assessment

The stock was benchmarked in January 2014 and a management plan evaluated and adopted (WKREDMP, ICES 2014). The benchmark group agreed to base the advice for next five years on the Gadget model. The settings are described in the Stock Annex.

### 19.4.1 Gadget model

### 19.4.1.1 Data and model settings

Below is a brief description of the data used in the model and model settings is given. A more detailed description is given in the Stock annex.

Data used in the Gadget model are:

- Length disaggregated survey indices $19-54 \mathrm{~cm}$ in 2 cm length increments from the Icelandic groundfish survey in March 1985-2021 and the German survey in East Greenland 1984-2020. The German survey index in 2018 is based on the average of the 2017 and 2019 values because the survey was not conducted in 2018.
- $\quad$ Survey indices are combined (Figure 19.4.2) and the German survey gets half the weight compared to what is presented in Figure 19.2.6. This was done to avoid extrapolation to areas not surveyed, and hence reduce noise. By using the stratification used to calculate indices shown in Figure 19.2.6, each station in the German survey would get 2.5 times more weight compared to the Icelandic survey.
- Length distributions from the Icelandic (1972-2021), Faroe Islands (1980-2020) and East Greenland (1975-2004) commercial catches.
- Landings by 6-month period from Iceland, Faroe Islands and East Greenland.
- Age-length keys and mean length at age from the Icelandic groundfish survey in October 1996-2020.
- Age-length keys and mean length at age from the Icelandic commercial catch 1995-2020.

Model settings:

- The simulation period is from 1970 to 2025 using data until the first half of 2021 for estimation. Two time-steps are used each year. The ages used were 5 to 30 years, where the oldest age is treated as a plus group (fish 30 years and older).
- Modelled length ranged between 19-54 cm.
- Commercial catches are split by country and implemented as separate fleets. Survey catch distribution data are modelled as a separate fleet.
- $\quad$ Recruitment was set at age 5 .

Estimated parameters are:

- Number of fishes when the simulation starts (8 parameters).
- $\quad$ Recruitment at age 5 each year (53 parameters).
- Length at recruitment (3 parameters).
- Parameters in the growth equation; (2 parameters).
- Parameter $\beta$ of the beta-binomial distribution controlling the spread of the length distribution.
- Selection pattern of the three commercial fleets assuming logistic selection (S-shape) ( $3 \times 2$ parameters).
- $\quad$ Selection pattern of the survey fleet assuming an Andersen selection curve (bell-shape) (3 parameters).

It should be noted that the length disaggregated indices are from the spring survey, but the age data are from the autumn survey conducted six months later. The surveys could have different catchability, but the age data are used as proportions within each 2 cm length group, so it should not have an impact on the results. Growth in between March and October is included in the model.

Assumptions done in the predictions:

- Recruitment at age 5 in 2022 and onwards was set as the average of the five smallest estimated year classes 1980-2007 or 41.7 million. The reason is indication of poor recruitment in recent years, but estimated recruitment was even lower.
- Catches in 2021 were set as the sum of expected landings, accounting for interannual transfer from 2020. Previously, the catches in the first time-step in 2021 (first 6 months) were set at the same as in the first time-step of 2020 for all the fleets; in step 2 in 2021 and onwards the model was run at fixed effort corresponding to $\mathrm{F}_{9-19}=0.097$. The NWWG concluded during the meeting in 2021 that the previous method of catch assumption in the intermediate year was seldom fulfilled as overshooting (catch exceeding the advice), especially in Icelandic waters, has ranged between $5-15 \%$ in recent years.
- The estimated selection pattern from the Icelandic fleet was used for projections.

### 19.4.1.2 Results of the assessment model

Summary of the assessment is shown in Figure 19.4.3 and Table 19.4.1. The spawning stock increased 1995-2015 but has since then decreased. Fishing mortality has been low since 2010, but since the HCR was adopted in 2014, the fishing mortality has been above the target of 0.097 because the catches have exceeded the advice. Recruitment (at age 5) after 2013 is at record low levels for the time series.

Assumptions about the cohorts after the 2015 one will not have much effect on the advice this year. This is because the average proportion of fish 10 years old and younger in the landings are only about $10 \%$. Later advice will be affected as well as the development of the spawning stock in short and medium term and is expected to decrease.

Although this year's assessment is consistent with previous assessments it shows a downward revision of SSB and an upward revision of fishing mortality compared to last year's assessment (Figures 19.4.4).

### 19.4.1.3 Mohn's rho

The retrospective pattern of the assessment (Figure 19.4.5) and the Mohn's rho values. The default five-year peels resulted in the following values:

| Variable | Value |
| :--- | :--- |
| Fbar | -0.0533 |
| SSB | 0.0352 |
| Rec. | 0.501 |

The Mohn's rho values for $\mathrm{F}_{\mathrm{bar}}$ and SSB are low ( $-5 \%$ and 3\% respectively) but indicates that fishing mortality has consistently been underestimated and SSB been overestimated (Figure 19.4.5). Mohn's rho for recruitment is on the other hand high ( $50 \%$ ) and indicates that recruitment has in previous assessments been overestimated. This value needs though to be taken with caution as recruitment estimates of the five-year peels is very low compared to previous years and any deviation from previous year may have relatively high impact. Extending the peel to, for example 10 years, may result in different value.

### 19.4.1.4 Diagnostics

Observed and predicted proportion by fleet: Trends in different likelihood components (Figure 19.4.6) shows how the fit to survey length distributions has become worse in recent years. This can also be seen in Figure 9.4 .7 where overall fit to the predicted proportional length distributions in the survey is smaller to the observed for medium sized fish ( $30-40 \mathrm{~cm}$ fish).

Length distributions from the Icelandic commercial catch does usually show good fit except in the most recent period when the large fish is missing and the length distribution narrower (Figure 19.4.8).

The fit between predicted and observed age distributions is better than for the length distributions (Figures 19.4.9 and 19.4.10). The model uses the data as age-length keys in 2 cm intervals for tuning.

Model fit: In Figure 19.4.11 the length disaggregated indices are plotted against the predicted numbers in the stock as a time-series. This lack of fit between observed and predicted numbers between 33 and 40 cm is caused by data conflicts with survey indices of larger sizes and compositional data. There appears to be an internal conflict between indices of lengths of 42 cm and above and the large number of smaller fish that was observed in the survey few years earlier. The model results are therefore a compromise between different data sets, and it is not able to follow the amount of $30-40 \mathrm{~cm}$ redfish in recent years. The inability of the model to fit the survey biomass in recent years has some support in the characteristics of the survey. Since 2003 most of the biomass in the Icelandic survey has been observed to be aggregated in very dense schools west of Iceland, caught on 5-10 stations every year. The size distribution in those schools is narrow and fish larger than 40 cm were rare.

As the model converges slowly, predicted indices could change several years back when more data are added. However, it is not the magnitude of the residuals but rather the temporal pattern that is worrying (Figure 19.4.12). For $35-42 \mathrm{~cm}$ fish, the observed indices have been above predictions for 5-11 years. The indices for $41-50 \mathrm{~cm}$ fish do not show such temporal pattern although in recent years the observed indices have been below prediction. The correlation between observed and predicted is good for $19-34 \mathrm{~cm}$ fish. When looking at the temporal patterns, longevity of the fish must be considered. Positive residuals in size groups $33-38 \mathrm{~cm}$ in recent years but negative for most other size groups, especially for fish smaller than 30 cm , indicates narrower length distributions in the survey than predicted (Figure 19.4.12).

### 19.4.2 Advice for 2021 (Last year's advice)

The management plan is based on $\mathrm{F}_{9-19}=0.097$ reducing linearly if the spawning stock is estimated below 220000 t ( $\mathrm{B}_{\text {trigger }}$ ). Blim was proposed as 160000 t , lowest SSB in the 2012 run. The 2020 SSB was estimated at $280100 t$, and according to the management plan the TAC advice for 2021 was 38343 t.

### 19.5 Reference points

Harvest control rule (HCR) was evaluated at WKREDMP in January 2014 (ICES, 2014) based on stochastic simulations using the Gadget model. Considering conflicting information by different data continuing for many consequent years (Section 19.4), the simulations were conducted using large assessment error with very high autocorrelation ( $\mathrm{CV}=0.25$, $\mathrm{rho}=0.9$ ).

Yield-per-recruit analysis show that when average size at age 5 was allowed to change after year class 1996, F9-19,MAX changed from 0.097 to 0.114 . The proposed fishing mortality of 0.097 is therefore around $85 \%$ of $\mathrm{Fmax}_{\mathrm{m}}$ with current settings. Stochastic simulations indicate that it leads to very low probability of spawning stock going below $B_{\text {trigger }}$ and $B_{l i m}$, even with relatively large autocorrelated assessment error.

At WKREDMP 2014, $B_{\text {lim }}=B_{l o s s}=160000 t$ was defined as the lowest SSB in the 2012 Gadget run. $B_{\text {trigger }}=B_{\text {pa }}$ was defined as $220000 t$ by adding a precautionary buffer to the proposed $B_{l i m}$ of $160000 \mathrm{t}: 160^{*} \exp \left(0.2^{*} 1.645\right)$. Recruitment in the stochastic simulations was the average of yearclasses 1975-2003 but those year-classes were the basis for the simulations at WKREDMP 2014.

The plot of the average spawning stock against fishing mortality show that $F_{\text {lim }}=0.226$ and $F_{p a}$ is then $0.226 / \exp \left(1.645^{*} 0.2\right)=0.163$ (Figure 19.5.1). The spawning stock decreased considerably from early 1980s to mid-1990s or from $400000 t$ to $200000 t$. The reduction in SSB was due to heavy fisheries but increased again gradually because of improved recruitment and lower F (Figure 19.5.1).

The probability of current $\mathrm{SSB}<\mathrm{B}_{\text {trigger }}$ is estimated $2.7 \%$. For simplicity, the action of $\mathrm{B}_{\text {trigger }}$ is not included in the simulations since Gadget is not keeping track of "perceived spawning stock". Analysis of the stochastic prediction in R shows that if SSB is below Btrigger it will only be noted in $<15 \%$ of the cases. The reason is that the spawning stock is only likely to go below $\mathrm{B}_{\text {trigger }}$ in periods of severe overestimation of the stock that occur due to the assumed high autocorrelation in assessment error. This situation differs from that of the stock going below Btrigger due to poor recruitment (worse than observed in recent decades). In this case the spawning stock should still have a resilient age structure (as discussed above) and this could reduce the need to take further action below B trigger.

Figure 19.5.2 shows the development of $\mathrm{F}_{9}-19$ based on $\mathrm{F} 9-19=0.097$. F is expected to be within the range of the fifth and $95^{\text {th }}$ quantile and the $16^{\text {th }}$ and $84^{\text {th }}$ quantile.

### 19.6 State of the stock

The results from Gadget indicate that fishing mortality has been low since 2009 but above Fmsy (Figure 19.4.3). Total biomass and SSB has been decreasing since 2016 (Table 19.4.1) and the absence of any indications of incoming cohorts raises concerns about the future productivity of the stock.

Results from surveys in Iceland and East Greenland indicate that most recent year classes are poor. The accuracy of the surveys as an indicator of recruitment is not known but recruitment is expected to be poor.

### 19.7 Short term forecast

The Gadget model is length based where growth is modelled based on estimated parameters. The only parameters needed for short term forecast are assumptions about size of those cohorts that have not been seen in the surveys. These year classes were assumed to be the average of five smallest year classes in 1980-2007 (Figure 19.4.3).

The results from the short-term simulations based on F9-19 is shown in Figure 19.4.3 and from short term prognosis with varying fishing mortality in 2022 and 2023 in Table 19.4.2. The results indicate that when fishing according to the management plan the SSB is expected to decrease further and to be close to MSY Btrigger in 2023 (Table 19.4.2).

### 19.8 Medium term forecast

No medium-term forecast was carried out.

### 19.9 Uncertainties in assessment and forecast

Various factors regarding the uncertainty and modelling challenges are listed in the WKRED 2012 (ICES, 2012) and WKREDMP-2014 (ICES, 2014) reports. In addition, this subject is discussed in Section 19.4.

### 19.10 Basis for advice

Harvest control rule accepted at WKREDMP 2014 (ICES, 2014) and implemented by Icelandic and Greenland authorities in 2014.

### 19.11 Management consideration

In 2009 a fishery targeting redfish was initiated in Subarea 14 with annual catches of between 6000 and 8500 t in 2010-2020, highest in 2015 and lowest in 2018. The fishery does not distinguish between species, but based on survey information, golden redfish is estimated to be between 1000 and 2700 in 2010-2015 but increased to $3000-5400 \mathrm{t}$ in 2016-2020.

Subarea 14 is an important nursery area for the entire resource. Measures to protect juvenile in Subarea 14 should be continued (sorting grids in the shrimp fishery).

No formal agreement on the management of $S$. norvegicus exists among the three coastal states, Greenland, Iceland, and the Faroe Islands. However, an agreement was made between Iceland and Greenland in October 2015 on the management of the golden redfish fishery based on the management plan applied in 2014. The agreement was from 2016 to the end of 2018. The agreement states that each year $90 \%$ of the TAC is allocated to Iceland and $10 \%$ is allocated to Greenland. Furthermore, 350 t are allocated each year to other areas. The plan has not been renewed so no management plan is effective although Iceland and Greenland still follow this plan.

In Greenland and Iceland, the fishery is regulated by a TAC and in the Faeroe Islands by effort limitation. The regulation schemes of those states have previously resulted in catches more than TACs advised by ICES.

Since 2009, surveys of redfish in the stock area have consistently shown very low abundance of young redfish ( $<30 \mathrm{~cm}$ ). Biomass (SSB and the harvestable biomass) increased from 1995 to 2015 because of recruitment of several strong year-classes to the stock. Since then, the biomass has declined. The absence of any indications of any incoming cohorts raises concerns about the future productivity of the stock.

### 19.12 Ecosystem consideration

Not evaluated for this stock.

### 19.13 Regulation and their effects

In the late 1980s, Iceland introduced a sorting grid with a bar spacing of 22 mm in the shrimp fishery to reduce the bycatch of juveniles in the shrimp fishery north of Iceland. This was partly done to avoid redfish juveniles as a bycatch in the fishery, but also juveniles of other species. Since the large year classes of golden redfish disappeared out of the shrimp fishing area, there in the early 1990s, observers report small redfish as being negligible in the Icelandic shrimp fishery. If the sorting grids work where the abundance of redfish is high is a question but not a relevant problem now in $5 . \mathrm{b}$ as abundance of small redfish is low and shrimp fisheries limited.

There is no minimum landing size of golden redfish in Division 5.a. However, if more than $20 \%$ of a catch observed on board is below 33 cm a small area can be closed temporarily. A large area west and southwest of Iceland is closed for fishing to protect young golden redfish.

There is no regulation of the golden redfish in Division 5.b.

Since 2002 it has been mandatory in the shrimp fishery in Subarea 14 to use sorting grids to reduce bycatches of juvenile redfish in the shrimp fishery.

### 19.14 Changes in fishing technology and fishing patterns

There have been no changes in the fishing technology and the fishing pattern of golden redfish in ICES subareas 5 and 14 .

### 19.15 Changes in the environment

No information available.

### 19.16 Benchmark

Benchmark meeting for golden redfish, scheduled in 2020 was delayed because of lack of resources within the ICES system. The group recommended that the stock should be benchmarked in 2023.

Golden redfish was last benchmarked in 2014 and the group thinks that benchmarking the stock is of high importance. The proposed benchmark meeting will explore several issues of current assessment model. These include poor fit to survey indices for fish between $30-40 \mathrm{~cm}$; potential dome-shape in selectivity; uncertainty estimates are not available; investigate the appropriateness of the current growth and maturity model used in the assessment. In addition, the meeting will explore alternative assessment methods. Underutilized data sources from ICES 5.b and 14.b, mainly relevant sur- vey and commercial samples of age and length. Biological reference points will need to be redefined depending on the assessment method, especially in relation to the Fp0.5. Change in form of harvest control rule will also be explored, that is change the rule to proportion of biomass above certain size (i.e. 33 cm and bigger fish) from the F based rule that is used now.

1) Provisional

Table 19.3.2 Golden redfish in 5.a. Observed catch in weight (tonnes) by age and years in 1995-2020. It should be noted that the catch-at-age results for 1996 are only based on three samples, which explains that there are no specimens older than 23 years.

### 19.19 Figures

Figure 19.2.1 Indices of golden redfish in ICES Division 5.a (Icelandic waters) from the groundfish surveys in March 19852021 (blue line and shaded area) and October 1996-2020 (red lines and shaded areas). The shaded areas represent 95\% CI.

Figure 19.2.2. Length disaggregated abundance indices of golden redfish from the bottom trawl survey in March 19852021 conducted in Icelandic waters. The blue line is the mean of total indices 1985-2021.

Figure 19.2.3. Length disaggregated abundance indices of golden redfish from the bottom trawl survey in October 19962020 conducted in Icelandic waters. The blue line is the mean of total indices 1996-2020. The survey was not conducted in 2011.

Figure 19.2.4 Age disaggregated abundance indices of golden redfish in the bottom trawl survey in October conducted in Icelandic waters 1996-2020. The survey was not conducted in 2011.

Figure 19.2.5 CPUE of golden redfish in the Faeroes spring groundfish survey 1994-2021 (blue line) and the summer groundfish survey 1996-2020 (red line) in ICES Division 5.b.

Figure 19.2.6 Golden redfish (> 17 cm ). Survey abundance indices for East Greenland (ICES Subarea 14) from the German groundfish survey 1985-2020. a) Total biomass index, b) total abundance index, c) biomass index divided by size classes (17-30 cm and $>\mathbf{3 0} \mathbf{c m}$ ). The survey was not conducted in 2018.

Figure 19.2.7 Golden redfish (>17 cm). Length frequencies for East Greenland (ICES Subarea 14) 1982-2020. The survey was not conducted in 2018.

Figure 19.3.1 Nominal landings of golden redfish in tonnes by ICES Divisions 1978-2020. Landings statistics for 2020 are provisional.

Figure 19.3.2 Geographical distribution of golden redfish bottom trawl catches in Division 5.a 2010-2020.

Figure 19.3.3 Length distribution (grey shaded area) of golden redfish in Icelandic waters (ICES Division 5.a) in the commercial landings of the Icelandic bottom trawl fleet 1976-2020. The blue line is the mean of the years 1976-2019.

Figure 19.3.4 Catch-at-age of golden redfish in numbers in ICES Division 5.a 1995-2020.

Figure 19.3.5 Catch curve of the 1981-2005 year-classes of golden redfish based on the catch-at-age data in ICES Division 5.a 1995-2020.

Figure 19.3.6 Length distribution of golden redfish from Faroese catches in ICES Division 5.b in 2001-2019.

Figure 19.3.7 CPUE of golden redfish from Icelandic trawlers 1978-2020 where golden redfish catch composed at least $50 \%$ of the total catch in each haul (black line), $80 \%$ of the total catch (red line) and in all tows where golden redfish was caught (blue line). The figure shows the raw CPUE index (sum(yield)/sum(effort)) and effort.

Figure 19.4.1 Stations in the German survey in East Greenland in 2020 with an area used to compile the indices for Gadget shown. This area corresponds to giving a weight of 0.5 to the results in Figure 19.2.7.

Figure 19.4.2 Biomass index from Iceland (blue) and Greenland (red), based on weighting the German survey data in Figure 19.2.7 by 0.5. In 2019, the survey index is based on the Icelandic survey and the average of the 2017 and 2019 values from the German survey in Greenland because it was not conducted in 2018.

Figure 19.4.3. Summary from the assessment in 2021.

Figure 19.4.4. Comparison of the current assessment (red line) and the same assessment done in 2019 (green line) and 2020 (blue line) for the total biomass, spawning stock biomass, fishing mortality and recruitment.

Figure 19.4.5. Analytical retrospective pattern of the base run. Recruitment is at age 5 and $F$ shows the development of ages 9-19.

Figure 19.4.6. Development of component of the objective function with time.

Figure 19.4.7. Fitted proportions-at-length from the Gadget model (black lines) compared to observed proportions in the spring survey (grey lines).

Figure 19.4.8. Fitted proportions-at-length from the Gadget model (black lines) compared to observed proportions from the Icelandic commercial catches (grey lines).

Figure 19.4.9. Fitted proportions-at-age from the Gadget model (black lines) compared to observed proportions in the autumn survey (grey lines).

Figure 19.4.10. Fitted proportions-at-age from the Gadget model (black lines) compared to observed proportions from the Icelandic commercial catches (grey lines).

Figure 19.4.11 Gadget fit to indices from disaggregated abundance by length indices from the spring survey.

Figure 19.4.12. Residuals from the fit between model and survey indices. The red circles indicate positive residuals (survey results exceed model prediction). Largest residuals correspond to $\log (\mathrm{obs} / \mathrm{mod})=1$

Figure 19.5.1. Average SSB against average fishing mortality and defined reference points.

Figure 19.5.2. Development of $\mathrm{F}_{9-19}$ based on $\mathrm{F}_{9-19}=\mathbf{0} \mathbf{0}$.097. The light grey area shows fifth and $95^{\text {th }}$ quantile and the dark areas $16^{\text {th }}$ and $84^{\text {th }}$ quantile.
