## Introduction

## A. Terms of reference and participation

In view of the continued decline of the Atlanto-Scandian herring stocks it was decided during the ICES Meeting in 1970 that the Working Group on Atlanto-Scandian Herring should meet again in order to compile new data and information on these stocks (C.Res.1970/2:8).

The Working Group met on 12 and 13 January 1971 in Charlottenlund Castle with the following scientistis participating:-

| Mr J Jakobsson, Chairman | Iceland |
| :--- | :--- |
| Mr O V Bakurin, | U.S.S.R. |
| Mr A C Burd | U.K. |
| Dr O Dragesund | Norway |
| Dr S S Fedorov | U.S.S.R. |
| Mr K Høydal | Faroes |
| Mr E J6nsson | Iceland |
| Mr K Popp Madsen | Denmark |
| Mr J J Zijlstra | Netherlands. |

Mr J Møller Christensen, Secretary of the Liaison Committee, also attended the meeting.

## B. Material and Agenda

The Working Group decided that the present report could only be considered as an appendix to its previous report (ICES, 1970), and that according to the terms of reference the Group would add all new available data to the various sections and tables in the previous report. In addition the Working Group decided to attempt new calculations on data from the small- and fat-herring catches in order to elucidate further the effect of this fishery on the Norwegian spring spawners.

The numbering of each section and of the tables in this report corresponds to that of the previous report. Also tables, where no new data could be added have been reproduced. Tables 22 and 23 are new.

## I. Description of stock units in the Atlanto-Scandian herring

The Working Group found that there was no need to add anything to the description given in its previous report (ICES, 1970) under this section.

## II. Norwegian spring spawners

II. a The adult herring fisheries

## A. Total catch

Tables 1 to 3 show the catches of adult and pre-recruit Norwegian spring spawning herring during the period 1950-1970. The catch figures for 1969 and 1970 show that the decline which started in 1967 has continued. Thus the total summer and autumn catch which in 1965-1966 amounted to about 1 million tons was only 3600 tons in 1969 and in 1970 the summer and autumn catch was practically nil (Table 1). The winter herring fishery decreased to 20500 tons in 1969. In 1970 this fishery was also very low, being 20900 tons. Consequently the total catch of Norwegian spring spawners which during the peak years in 1965-1967 amounted to some 1.5 million tons was reduced to about 20000 tons during the two previous years. Figure 1 illustrates how the stock size as well as the total catch have decreased in the last few years while the small- and fatherring fishery's proportion of the total catch has rapidly increased.

## B. Effort

Table 4 shows that the total number of vessels participating in the herring fisheries based on Norwegian spring spawners has decreased drastically in recent years. Thus the number of participating Norwegian purse-seiners was 418 in 1967 but in 1969 and 1970 there were 128 and 129 respectively. The number of Icelandic purse-seiners was reduced from 139 in 1967 to 25 in 1969 and nil in 1970.

Similarly the Soviet drifter fleet decreased from 342 in 1967 to 79 in 1969 and nil in 1970. At its meeting in 1969 the Working Group decided to use Soviet drifter units for effort and catch per effort estimates. Since this fishery was completely stopped in 1970, only estimates for 1969 could be added to Tables 5 and 6. The total effort in drift-net units which in 1967 was about 20 millions was in 1969 reduced to about 1 million nets or less.

## C. Age composition

The percentage age composition as presented in Tables 7 and 8 shows that the catches in 1969 and 1970 are based on the same year classes as in say 1966-1968. Thus the year classes from 1959, 1960 and to some extent from 1961 are still the predominant ones there being no sign of increased recruitment to the adult stock. It is of special interest to note that the year classes from 1963 and 1964 which according to the 0 -group surveys were of average strength and gave rise to rich immature fishery in 1965-1968 are quite negligible in the age composition of the adult stock.

## D. Estimates of absolute stock abundance

Unfortunately there were no new estimates available of absolute stock abundance. As a result of the small catches in recent years practically no adult herring has been used for reduction purposes and hence tagging returns have been negligible. In spite of repeated attempts Soviet scientists have not been able to carry out their stock estimates based on echo-surveys because herring concentrations could not be located for this purpose. In the absence of new estimates the Working Group decided not to attempt extrapolation of older data for this purpose although such methods could give some rough estimates of absolute stock abundance (probably about 0.7 million tons in 1970 assuming no changes in M).

It is of interest to note that the fluctuations of the Soviet catch per drift net during February as presented in Table 5 correspond to those of the absolute stock abundance estimates based on tagging data or echosurveys. Therefore it is possible to consider the catch per unit effort of the Soviet fleet during February as a stock abundance index completely independent from the other two presented in Table 16.

## E. Mortality rates

Owing to the complete breakdown of the fisheries in recent years it has become impossible to calculate comparable mortality rates for the adult Norwegian spring spawners.

## II.b The imnature herring fisheries

In the former report (ICES, 1970) attention was drawn to the probable serious effect of the increased exploitation rate on fat herring.

With more extensive data available it has been possible to make new estimates of the numbers of herring in the small- and fat-herring catches. These estimates are now based on revised age distributions and on relevant mean weights per age group per season (Table 19). A revised set of abundance indices of 0-group herring is also included in the table. With the revisions in catches, changes in the exploitation rates of both small and fat herring occurred. These are shown in Figure 2 and indicate an increasing rate of exploitation in the smallherring fisheries. In the fat-herring fishery, however, the exploitation dropped after the very high levels on the 1963 and 1964 year classes but increased again on the most recent year classes.

In its previous report (ICES, 1970) the Working Group drew attention to the probable reduction in recruitment to the adult stock of the 1963 and 1964 year classes. The present Working Group has examined the problem in more detail. An attempt has been made to compare the stock size in numbers as 3 year olds (the fat herring stage) with the catches in number from the fat-herring fisheries. The stock sizes of a number of year classes have been compared with the abundance indices of these classes as 0-groups.

From the data in Table 9 the catches in number of $6-8$ year olds have been taken as indices of fully recruited herring. Using estimates of $F$ derived from Tables 13 and 16 stock sizes in number for the 1959-1962 year classes have been calculated for the year of assumed full recruitment using

$$
C=S \cdot \frac{F}{Z}\left(1-e^{-Z t}\right)
$$

A value of $M=0.15$ has been assumed (ICES, 1970) for all ages down to age 3 the herring being then over 20 cm . Previous years' stock levels of a year class were derived from the relation:-

$$
S_{n-1}=S_{n} \cdot e^{M}+c_{n}
$$

The maximum estimates of year class strength derived by this method are shown in Table 22, where they are compared with the estimates of the same year classes as 0-group herring derived from echo-sounding techniques (Dragesund, 1970). It is seen that there is good agreement in the
relative year class strength for all except the 1962 year class. This year class was very weak in the adult catches but was heavily exploited as small herring (ICES, 1970).

Assuming that the 0-group abundance (Dragesund and Nakken, 1970) are comparable over the whole period to $1969^{1)}$, it is possible to make estimates of the potential stock sizes of the year classes as 3 year old fish from the ratios given in Table 19 (column a). These estimates are given in Table 23 (column a) together with the fat herring catches of each year class in number. Considering the year classes 1959-1961 the exploitation rate in the fat herring stage, and not including the small herring, would appear to have varied between about 10-50\%.

It can be seen that in some year classes the numbers of herring caught in the fatherring fishery approach or exceed the total stock estimate given by back calculation. In view of the assumption made on mortality coefficients in the adult herring and the low sampling rate in the fatherring fisheries relative to their complicated nature, these results are well within the range of expectancy. They imply that the fatherring fishery practically annihilated the 1963 and 1964 year classes as was tentatively suggested in the previous report (ICES, 1970).

Dragesund (1970) using a different technique on the 1963 year class came to the same conclusion. The failure of the 1963 and 1964 year classes to recruit to the adult fisheries as shown in Table $\mathcal{G}$ could thus be consequent to the exploitation of the juvenile herring.

## II.c Changes in the migration pattern

The recent drastic changes in migration pattern of the Norwegian spring spawners were schematically shown on Charts $1-3$ of the previous report (ICES, 1970). In addition to these changes in migration pattern the shoaling behaviour of the Norwegian spring spawners has changed drastically during the last few years. Thus instead of assembling into dense over-wintering concentrations the herring has since 1968 been widely scattered. This holds true for practically the whole year with very sporadic and infrequent exceptions.

[^0]
## III. The Icelandic herring stocks

The report of the Working Group on Atlanto-Scandian Herring (ICES, 1970) dealt with the catch statistics of the Icelandic herring stocks during the period 1957-1967. In Table 20 these are extended to 1970. The catch during the last few years has been very low as expected or about 20000 tons per year. The regulations described in the previous report (ICES, 1970; see also Jakobsson, 1969) are still in force and the fishing effort is thus greatly reduced as compared with the earlier years of unrestricted fisheries. Since practically no herring has been used for reduction purposes in Iceland since 1967, estimates of absolute abundance based on tagging data are not available for the last three years. At present, data on stock abundance are therefore not available for 19681970 but recent trends in age composition (Jakobsson, Annls.biol., Copenh., 25:147 and 26:165) tend to indicate a decrease in annual total mortality which is probably due to less fishing intensity than before. There can, however, be no doubt that the abundance of the Icelandic stocks is still at a very low level.

## IV. Causes of the recent decline in the yields of the Atlanto-Scandian herring

The Working Group found that the development in 1969 and 1970 of the herring fisheries based on adult Norwegian spring spawners confirmed the statement made in the previous report (ICES, 1970), that the causes for the recent drastic decline in these fisheries are primarily due to lack of recruitment since there has been practically no recruitment to the adult stock since the 1959-1961 year classes were fully recrivited in 1966. This decline of the stock was accelerated by higher exploitation rate in recent years, especially during the period 1965-1967. Since 1968 the low availability of the herring has caused a sharp decline in effort due to diversion to other stocks. To some extent this has probably resulted in a lower exploitation rate in the adult stock during the last three years.

As regards recruitment to the adult stock in the coming years, the results from the Norwegian and international echo-surveys show that the 1962 and 1965-1970 year classes are all very poor. The 1963 and 1964 year classes, which were estimated to be of reasonable strength as 0group fish were so heavily exploited in the fat herring stage that
their recruitment to the adult stage has been negligible. Similarly, the exploitation rate of the 1969 year class as fat herring appears to be very high or at about the same order as the 1963 and 1964 year classes. The other small year classes in recent years (1965-1968) have probably not suffered such a high exploitation rate in the fat herring stage but in contrast they were exploited more heavily in the small herring stage. Thus the recruitment to the adult stock from the poor year classes in recent years (1965-1969) is expected to be almost nil. At present the Norwegian spring spawning stock of herring appears to be in a phase of very low reproductive potential.

In view of the present critical state of the stock it would be advisable in order to maximize recruitment and safeguard the continued existence of the Norwegian spring spawning stock to keep the exploitation rate of small and fat herring at a much lower level than in recent years. The adjustment of this exploitaion rate should be made relative to the independent estimates of year class strength derived from O-group surveys rather than by arbitrary catch adjustment.
